

Sporadic Meteors

Abstract

It turns out that some sporadic meteors are not so random after all. There are groups of nonshower meteors that encounter Earth on a daily basis, adding a few meteors per hour to the overall activity. Some of these are actually artificial radiants that are created by Earth's motion through space. Only one of these radiants produces enough activity to be easily seen by the visual observer. This radiant would be the Antihelion radiant, so named as the radiant's location lies opposite the Sun. Details of the position and periodic enhancements of the Antihelion shower are listed in the outbound counterpart of the Antihelions, the Helion radiant, is just as active but unfortunately lies in the direction of the Sun and is therefore unobservable by visual means.

2.1 Random Meteors

A great majority of the meteors you see in the sky above are sporadic, not belonging to any recognizable shower. The material that produces meteor showers is constantly evolving with meteoroids being spread out throughout their orbit. Not only do they spread material throughout the orbit in an organized manner, but the smaller particles are also pushed farther from the Sun by the solar wind and larger particles are pulled toward the Sun by its intense gravity. These forces tend to disperse organized meteoroids as time progresses. The dispersion process can take a few hundred years up to several thousand, depending on the interaction of the major planets. What is a random meteor today may have belonged to an organized meteor shower a thousand years ago. A thousand years from now a Geminid meteor may go unrecognized amid other new showers that have formed.

When maximum hourly rates fall below 2 per hour a meteor shower becomes difficult to recognize. The odds a sporadic meteor will line itself up with any shower radiant is at least 1 per hour. Therefore a weak shower producing one meteor per hour can suffer from sporadic contamination, artificially doubling its true activity. Meaningful meteor shower lists limit themselves to showers that produce hourly rates of at least two shower members at maximum activity. This means that the observer will actually witness an average of three meteors per hour from these showers, with one of the meteors actually being sporadic. This is meaningful, for weak showers producing ten meteors an hour or less as a large percentage of

their activity can actually be associated with random activity. For stronger showers this is a smaller percentage of the observed activity and does not skew the results.

Like shower activity, sporadic rates vary throughout the year, depending on your location. From the northern hemisphere the spring season offers the lowest sporadic rates of the year. During the summer sporadic rates increase and reach a 3-month maximum during the months of autumn. The winter season offers good rates in January, but activity falls during February and March toward the spring low (Fig. 2.1). In the southern hemisphere the activity curve is not so simple. Their summer season produces a peak of sporadic activity in January, with rates then falling slowly during February and March. Sporadic rates again increase in April and May toward a secondary maximum in July. In August rates fall steeply toward the annual minimum in October. In November rates again climb toward the January maximum (Fig. 2.2).

It was once thought that the annual variation in sporadic activity was due to the angle of the ecliptic during the active morning hours. As seen from the northern hemisphere the angle of the ecliptic is steepest near the autumnal equinox in September. The angle is shallowest near the spring equinox in March. This roughly coincides with the strongest and weakest sporadic rates of the year. One would expect just the opposite as seen from the southern hemisphere with the strongest rates in March and the weakest in September.

Fig. 2.1. Mean annual sporadic rates as seen from 45°N, under dark sky conditions.

Fig. 2.2. Mean annual sporadic rates as seen from 45°S, under dark sky conditions.

Fig. 2.3. Diurnal sporadic rates showing the peak near 6:00 a.m.

The September minimum is correct, but the peak in June/July and the secondary minimum in March do not fit at all. Therefore the ecliptic angle has little effect on the sporadic activity. The lack of data from the southern hemisphere hampers the study, but it is currently thought that the solution is simply that the lulls in sporadic activity is due to a genuine lack of material located north or south of the ecliptic plane encountering Earth at that time of year (Fig. 2.3).

No matter your location, the time of day has a great influence on the number of sporadic meteors you will see. At 6:00 p.m., when you look into the sky, you are viewing the area of space from which Earth is receding. This is much like the view out the back window of a moving vehicle in rainy weather. To be seen at this time any meteoroid must overtake Earth. Like the scarcity of raindrops on a rear window, there are very few meteoroids that catch up to Earth and can be seen at this time. The situation slowly improves as the evening progresses. Near 9:00 p.m. Earth has rotated 45° toward the east, yet the situation has scarcely improved. Any activity seen at this hour is a combined group of meteors catching up to Earth and those striking the atmosphere at a more perpendicular angle. Rates are still relatively low at midnight, with all activity striking Earth at near-perpendicular angles.

A particular group of meteors radiating from the ecliptic near the opposition (antisolar) point is often noticeable at this time. These are the Antihelion meteors, separate from sporadic meteors yet not produced by any single object. These meteors will be presented in the next chapter.

Past midnight observers will begin to see meteors that strike Earth from a head-on direction. As the graph implies, many more meteors are seen after midnight than before. The reason for this is that the observer can now see meteors from both perpendicular angles and those striking the atmosphere head on. During the early morning hours, near 3:00 a.m., an observer is now viewing the part of the sky to which Earth is approaching. There will still be some slower meteors radiating from areas in the western half of the sky, produced by meteors striking the atmosphere at a more perpendicular angle. The most notable and more numerous meteors, though, will be those radiating from the eastern half of the sky with very swift velocities. The maximum diurnal rates occur near 6:00 a.m., when nearly all meteors seen strike Earth from a head-on direction. This situation is much like viewing through the front windshield of a moving vehicle during rain. Unfortunately dawn interferes at this hour, so the best observed rates usually occur an hour or two earlier before the onset of morning twilight.

2.2 Antihelion Meteors

During the course of a year Earth intercepts particles orbiting in a prograde motion lying in low-inclination orbits centered along the ecliptic. Like most members of the Solar System these particles orbit the Sun in a direct motion and encounter Earth before their closest approach to the Sun. The source of these meteoroids is not precisely known, but it is thought that they are produced by asteroids or comets under the gravitational influence of Jupiter. These meteoroids that encounter Earth on the inbound portion of their orbit are known as Antihelion meteors. They are named for the area of the sky in which they seem to radiate, the antisolar or Antihelion portion of the sky. This part of the sky rises as the sky becomes totally dark and is best placed near 0100 local standard time (LST), when it lies highest above the horizon. During the morning hours the Antihelion radiant sinks into the western sky and lies near the western horizon at dawn. The radiant is not precisely located at the antisolar point due to the fact that slower meteors, such as the Antihelions, are affected by the apex attraction. Simply stated, the apex attraction is produced by Earth's motion through space, which causes the apparent radiant to be slightly different than the actual radiant. In this case the apparent Antihelion radiant is shifted 15° toward the direction Earth is moving (east). Therefore the apparent radiant of the Antihelion meteors lies 15°E of the exact antisolar point.

These meteors were once classified into separate showers throughout the year, with their radiant area always near the antisolar area of the sky. Among these were the delta Cancriids of January, the Virginids of February, March, and April, the alpha Scorpiids of May, the Sagittarids of June, the Capricornids of July (not to be confused with the alpha Capricornids), the iota Aquariids of August, the Southern Piscids of September, the Arietids of October, the Taurids of November (not to be confused with the Northern and Southern Taurids), and lastly the chi Orionids of December.

Observers rarely focus on viewing the Antihelion radiant, as rates seldom exceed 3 per hour. There is, though, a constant supply of slow meteors produced from this area throughout the night and during the course of a year. Rarely does an observer not see at least one Antihelion meteor during an observing session. Unlike most shower radiants, the Antihelion radiant is large and diffuse, often covering an area of 30° in right ascension (celestial longitude). The size in declination (celestial latitude) is somewhat less, making it oval shaped.

As stated before, these meteors are visible during the entire night but best seen near 1:00 a.m. LST when the radiant lies on the meridian and is situated highest in the sky. For those who observe summer or daylight saving time the culmination would occur at 2:00 a.m. Since the Antihelion radiant does not venture more than 23° from the celestial equator, shower members may be seen equally well from both hemispheres during the year. The radiant follows the ecliptic and ranges from a declination of 23°N in late November and early December to 23°S in late May and early June. Therefore it is best seen in late November and early December from the northern hemisphere and from late May to early June from the southern hemisphere.

During October and November the large Antihelion radiant overlaps that of the more active north and south Taurid radiants. During this time it is impossible to separate activity from these radiants. Therefore, at this time of year any activity from this area is classified as either northern or southern Taurid. This may artificially inflate the observed activity of the Taurids, but at this time it is the best compromise (Table 2.1)

There are certain times of the year when the Antihelion radiant is slightly stronger than its normal 2-3 meteors per hour. These were once thought to be the peaks of separate showers. In reality it's just areas where the concentration of particles is just a bit higher than normal. Table 2.2 lists these periods of enhanced rates for the Antihelion radiant.

Table 2.3. Helion showers³

Name	Period	Maximum	Position
Daytime Scutids	Dec 30–Jan 06	Jan 04	278 (18:32) – 08

2.3 Helion Meteors

These meteors are similar to the Antihelion meteors only in that they strike Earth on the outbound leg of their orbit. Therefore they strike the sunlit portion of Earth and are seldom seen. This radiant follows the ecliptic and is normally located only 15°E of the Sun. They are never seen in total darkness, as the Sun must be 18° below the horizon for total darkness to exist. The only opportunity of ever seeing these meteors would be from near the equator, where twilight is at its shortest. Even then the chance is remote, as the low elevation of the radiant would provide only a small fraction of the meteors seen compared to when the radiant is located highest in the sky.

Radar studies of the sky have revealed numerous showers associated with the Helion radiant. Table 2.3 lists the showers from the IAU associated with the Helion radiant.

2.4 Apex Meteors

Material that circles the Sun in a high-inclination orbit in a retrograde motion is most likely produced by Halley-like and long-period comets. This material encounters Earth after perihelion on the outbound portion of its orbit. Since they are moving in opposite directions they strike Earth at tremendous velocities often creating bright meteors with persistent trains. These particles strike Earth on the morning side of the planet and are best seen just before morning twilight, while the sky is still perfectly dark. This is not really a shower per se but an artificial radiant created by Earth's motion through space. Unlike the Antihelion radiant, which is always located on the ecliptic, the apex radiants have formed two diffuse branches located approximately 15°N and 15°S of the ecliptic, 90°W of the Sun. Therefore it rises near midnight and is highest in the sky near 6:00 a.m. LST.

One theory for the formation of the two branches is that Earth has cleared away much of the material near its orbit (zero inclination), leaving most of the material either north or south of the ecliptic. Studies of these meteors made by members of

Table 2.4. Periods of enhanced apex activity⁴

Period	Maximum	Position

Aug 12–17	Aug 15	040 (02:40) + 36
Aug 19–30	Aug 24	058 (03:52) + 41
Aug 24–30	Aug 30	074 (04:56) + 15
Aug 28–Sep 08	Sep 06	066 (06:24) – 03
Sep 16–23	Sep 21	074 (04:56) + 08
Oct 24–Nov 04	Nov 03	149 (09:56) + 28
Nov 06–11	Nov 08	146 (09:44) + 45
Dec 09–16	Dec 09	179 (11:56) + 35

the American Meteor Society (AMS) have revealed that these meteors are less numerous than those of the Antihelion radiant, and that attempts to isolate these meteors from the sporadic background are for the most part not worthwhile. There are times during the year, though, when rates from the apex source are more noticeable. Table 2.4 lists these periods along with the radiant positions.

2.5 Antiapex Meteors

Antiapex, or antapex, meteors are produced by material orbiting the Sun in a retrograde direction that encounters Earth on the inbound or preperihelion portion of its orbit. Like the sources that produce the apex meteors, these are most likely produced by long-period comets. These meteors have twin radiants located north and south of the ecliptic, 90°E of the Sun. This means they are best seen as soon as it becomes dark, after the end of evening twilight. Once again this is not a true shower but an artificial radiant created by Earth's motion through space. Unlike the apex meteors, these meteors would be among the slowest to appear in the sky. Slow meteors are affected by Earth's gravity in such a way that the apparent radiant is actually far from the true radiant. This is called the *zenith attraction*. With the diffuse nature of the radiant, the additional offset due to the *zenith attraction* would make classifying these meteors very difficult. The radiant area would be so large that fully half of the few evening meteors seen could possibly be members of the antapex group. Since this is an artificial radiant it is advised that observers simply label these meteors as sporadic and save their efforts for true shower meteors.

When the antapex radiant lies highest in the sky there seems to be an increase in the fireball activity. Studies have shown that during the period from mid-February through mid-April, when the antapex radiant lies highest in the sky, fireball rates peak as seen from the northern hemisphere. If this relationship is true then the same scenario should occur during mid-August to mid-October from the southern hemisphere. Unfortunately the lack of observers located south of the equator has prevented this from being verified.

Table 2.5. Parameters of the N. Toroidal showers found in the IMO's video study⁶

Period	Maximum	Position	Expected position
Mar 30–Apr 07	Mar 31	276 (18:28) + 41	277 (18:32) + 27
Sep 29–Oct 05	Oct 04	080 (05:20) + 83	114 (07:36) + 73
Oct 06–11	Oct 07	079 (05:16) + 82	120 (08:00) + 72
Nov 23–29	Nov 29	199 (13:16) + 65	187 (12:28) + 53
Dec 06–23	Dec 20	209 (13:56) + 56	204 (13:36) + 45

2.6 Toroidal Meteors

There is a group of meteoroids in orbits inclined steeply to the ecliptic that encounter Earth on a continual basis. The source of this material is not known, but it is thought to be related to the Jupiter family of comets, the same source of the Helion and Antihelion meteors.⁵ Rates from this source are less than those seen from the other sporadic groups. This diffuse radiant would be centered approximately 90°W of the Sun and 50° north and south of the ecliptic. These meteors, striking the atmosphere at near-perpendicular angles, would have an entry velocity of 22 miles/s, which would result in meteors of medium velocity.

Several showers that can be identified with the northern Toroidal source have been found in Sirko Molau's analysis of the IMO's video database, though not always in the exact position expected. This indicates a large and diffuse radiant. Reported dates and positions are listed in Table 2.5.

Of the six periods listed, the last period in December provided far and away the strongest rates. Due to the lack of data from the southern hemisphere no showers from the southern Toroidal source were found. Visual observers would have a difficult time trying to separate any possible Toroidal meteors from the sporadic background, especially when sporadic rates are high.
