Chapter 2
Anatomy and Biomechanics of the Cruciate Ligaments and Their Surgical Implications

Christopher Kweon, Evan S. Lederman, and Anikar Chhabra

2.1 Introduction

Multiple ligament knee injuries, although rare, are severe injuries that often result in the loss of the passive and active knee stabilizers as well as often being associated with the compromise of neurovascular structures. Treatment of these injuries is controversial, and results after surgery are often poor. After sustaining injuries to multiple ligaments, the knee is at a biomechanical disadvantage which poses a reconstructive and rehabilitative challenge to even the most experienced orthopedic surgeon. Surgeons performing reconstructions in patients with these injuries must have a complete understanding of the normal anatomy and biomechanics of the knee to optimize the timing of surgery, surgical approach, tunnel preparation, and the anatomic placement of grafts. This chapter outlines the anatomy and biomechanics of the cruciate ligaments and their surgical implications. The structure and form of the anterior and posterior cruciate ligaments, patterns of injury, structural properties of the cruciate ligaments and graft substitutes, functional biomechanics and interplay between the cruciate ligaments, and the surgical implications related to anatomic reconstruction of the anterior and posterior cruciate ligaments are all reviewed in detail.

2.2 Anatomy of the Cruciates

2.2.1 Anterior Cruciate Ligament Anatomy

The anterior cruciate ligament (ACL) extends from a broad area anterior to and between the intercondylar eminences of the tibia to a semicircular area on the posteromedial portion of the lateral femoral condyle. It not only prevents anterior translation of the tibia on the femur but also allows for normal helicoid knee action, thus preventing the chance for meniscal pathology. It is composed of two bundles that are named based on their relative attachments on the femur and tibia: an anteromedial bundle, which is tight in flexion, and a posterolateral bundle, which is more convex and tight in extension (Fig. 2.1) [1, 2]. While there are reports in the literature that suggest up to 26% of knees with microscopic single bundle ACLs as well as knees that have a third intermediate bundle, it is now generally accepted that the native ACL consists of two discrete bundles [3, 4].

Anatomic studies have shown that the ACL ranges from 31 to 38 mm in length and 10 to 12 mm in width [5]. The anteromedial bundle on average measures 6–7 mm in width, while the posterolateral bundle measures 5–6 mm [3, 4].

Recently, the study of the ACL along with its osseous footprint and associated topographical anatomical landmarks has clarified the understanding of ACL anatomy. On the femur, the lateral intercondylar ridge (sometimes referred to as resident’s ridge) and the lateral bifurcate ridge (also known as the cruciate ridge) are utilized to identify the discrete attachment points of the anteromedial and posterolateral bundles of the ACL on the lateral femoral condyle [6]. The two bundles of the ACL attachments are separated by the lateral bifurcate ridge just posterior to the lateral intercondylar ridge (Fig. 2.2). On the tibia, the medial and lateral intercondylar tubercles have been described in relation to the distal attachment sites for both bundles of the ACL (Fig. 2.3) [6, 7]. These osseous landmarks have become increasingly important reference points during arthroscopy and cruciate ligament reconstruction.

The ACL is intra-articular; however, it is encased in its own synovial membrane. The vascular supply of the ACL is derived from the middle genicular artery, as well as from diffusion through its synovial sheath [8]. The innervation of the ACL consists of mechanoreceptors derived from the tibial nerve and contributes to its proprioceptive role [9, 10]. Pain fibers in the ACL are virtually nonexistent, which explains why there is minimal pain after an acute ACL rupture prior to development of a painful hemarthrosis [11].
2.2.2 Posterior Cruciate Ligament Anatomy

The posterior cruciate ligament (PCL), like the ACL, is intra-articular and extrasynovial, with a much larger part existing extrasynovially. It extends from a broad semicircular area on the lateral aspect of the medial femoral condyle and projects to a sulcus that is posterior and inferior to the articular plateau of the tibia. The PCL consists of two bundles: a larger anterolateral bundle, which is tight in flexion, and a smaller posteromedial unit, which is tight in extension (Fig. 2.4) [12, 13]. Its average length and width at its midportion, as reported by Girgis et al., are 38 and 13 mm, respectively [14]. The PCL cross-sectional area is 50% greater than the ACL at the femur and 20% greater at the tibia. In contrast to the ACL, the PCL is larger at its femoral insertion than at its tibial insertion [12]. Two intra-articular accessory ligaments, the meniscofemoral ligaments, extend from the posterior horn of the lateral meniscus and insert anterior and posterior to the PCL onto the medial femoral condyle. These are termed the ligaments of Humphrey and Wrisberg, respectively, and are not present in all knees. They average approximately 22% of the entire cross-sectional area of the PCL [12]. They serve as secondary stabilizers to posterior tibial translation (Fig. 2.5).
As with the ACL, PCL attachments on the femur and tibia are more complex than originally understood, and there exists some variance between individuals. The femoral footprint for the PCL on average measures 209 mm$^2$ with the anterolateral portion measuring 118 mm$^2$ and posteromedial insertion measuring 90 mm$^2$ [15]. The medial intercondylar wall and medial bifurcate ridge have been described as osseous landmarks on the femur in relation to the site of attachment of the PCL. On the tibia, the surface area for the PCL attachment is 244 mm$^2$ on the posterior intercondylar fossa between the tibial plateaus one centimeter distal to the joint surface with the anterolateral and posteromedial insertions measuring 93 and 151 mm$^2$, respectively [16].

The vascular supply of the PCL is similar to that of the ACL since both are derived from the middle genicular artery. The vascular supply is mainly soft tissue based, not osseous based [17]. The innervation of the PCL is from the tibial and obturator nerves. As with the ACL, this serves primarily as a proprioceptive function [9].

### 2.2.3 Vasculature of the Knee

Branches of the femoral and popliteal arteries supply the knee and its structures. The descending geniculate artery is a branch of the femoral artery proximal to Hunter’s canal and supplies the vastus medialis at the anterior border of the intermuscular septum. The medial and lateral geniculate arteries wrap around the distal femoral condyles and supply the menisci, while the middle geniculate artery supplies the cruciate ligaments [17]. The superior lateral geniculate artery is often injured during lateral release procedures, while the inferior lateral geniculate artery is often injured during posterolateral corner reconstructions (Fig. 2.6) [23].

The geniculate arteries, the descending branch of the lateral circumflex femoral artery, and the recurrent branches of the anterior tibial artery form the anastomosis around the knee that connects the femoral, popliteal, and anterior tibial arteries.

### 2.2.4 Injury Patterns of the Cruciate Ligaments

The injury pattern of both the cruciate ligaments and their discrete bundles has not been well studied. While the classic presentation and mechanism of injury leading to isolated ACL and PCL injuries is well described, combined multiligament injuries are often due to higher energy injuries. The anteromedial bundle of the ACL is more commonly torn from its femoral attachment site, whereas the posterolateral bundle is often torn at its midsubstance. The majority of ACL injuries involve complete rupture of both bundles with a 12% showing a completely intact posterolateral bundle [18]. Injury patterns of the
PCL are not as well described in the literature but can consist of injury to the posteromedial, anterolateral, or both bundles. The surgical implications of single- versus double-bundle reconstruction as it relates to the discrete injury patterns have become increasingly more important as our understanding of cruciate anatomy has increased.

### 2.3 Biomechanics of the Cruciates

#### 2.3.1 Biomechanics and Kinematics of the Knee Joint

The goal of all joints is to allow for motion of the bony segments surrounding the joint while withstanding the loads against gravity imposed by these movements. Biomechanics is defined as the science of the action of forces on the living body. The complex interaction of femur, tibia, and patella allows the knee joint to withstand tremendous forces during normal phases of ambulation. Kinematics is defined as the study of body motion without regard for the cause of that motion [23]. Six planes of motion exist for the knee: anterior/posterior translation, medial/lateral translation, cephalad/caudad translation, flexion/extension, internal/external rotation, and varus/valgus angulation [22]. The knee joint must provide a normal amount of motion without sacrificing stability during static activities such as standing to more dynamic functions such as walking, jogging, running, pivoting, and ascending or descending stairs. These goals are achieved by the interaction of the osseous anatomy, articular surface, ligaments, menisci, and surrounding musculature about the knee [24]. Changes in any of these components can alter the biomechanics of the knee joint, greatly increasing the loads and functional demands placed on the remaining structures. Understanding the normal interactions of these structures is necessary prior to attempting any reconstructive procedures.

#### 2.3.2 Passive Motion of the Knee

The primary motion of the knee is flexion and extension. The knee joint averages from 0 to 135° of flexion in the sagittal plane [2]. The passive motion of the knee joint is dictated by the anatomy of the articular surfaces and the surrounding soft-tissue capsule and ligaments [25]. As a result of the distal asymmetry between the medial and lateral femoral condyles, motion
between full extension and 20° of flexion is accompanied by rolling of the lateral femoral condyle posteriorly more than the medial femoral condyle. This allows the femur and tibia to unlock from full extension and occurs without the assistance of any dynamic muscle involvement [24]. After 20° of flexion, passive flexion of the knee joint occurs by a sliding motion, with relative tibial movement on the femur [2].

2.3.3 The Functional Biomechanics of the Cruciate Ligaments

Of the knee ligaments, the cruciates are the most important in providing passive restraint to anterior/posterior knee motion. If one or both of the cruciates are disrupted, the biomechanics during ambulatory activities may be disrupted. The interplay between the cruciate ligaments, the collateral ligaments, and the other static and dynamic stabilizers of the knee is complex, and an appreciation for the osseous, articular, meniscal, tendinous, and other soft-tissue components that contribute to overall knee motion and stability is important.

2.3.4 Biomechanics of the ACL

The primary function of the ACL is to prevent anterior translation of the tibia. It acts as a secondary stabilizer against internal rotation of the tibia and valgus angulation at the knee [26, 27]. In full extension, the ACL absorbs 75% of the anterior translation load and 85% between 30 and 90° of flexion [28]. Loss of the ACL leads to a decreased magnitude of this coupled rotation during flexion and an unstable knee. Many studies have been performed to determine the biomechanical properties of the ACL. However, uniform testing with regard to strain rates and orientation is impossible. Several recent studies have demonstrated that the anterior bundles (both medial and lateral) have higher maximum stress and strain than the posterior bundles [29]. The tensile strength of the ACL is approximately 2,200 N but is altered with age and repetitive loads [19, 23, 30]. As the magnitude of the anterior drawer force increases, the in situ force of the ACL also increases [5].

2.3.5 Biomechanics of the PCL

The primary function of the PCL is to resist posterior translation of the tibia on the femur at all positions of knee flexion [31]. It is a secondary stabilizer against external rotation of the tibia and excessive varus or valgus angulation at the knee [32]. The anterolateral band is tight in flexion and is most important in resisting posterior displacement of the tibia in 70–90° of flexion. The posteromedial portion is tight in extension; thus, it resists posterior displacement of the tibia in this position. While the PCL is the primary restraint to posterior translation of the tibia, this function is greatly enhanced by other structures [33, 34]. Recent cadaveric studies have suggested that excessive posterior translation of the tibia requires injury to one or more secondary structures in addition to the PCL [35].

Isolated PCL ruptures may cause a mild increased in external rotation at 90° of knee flexion; they do not greatly alter tibial rotation or varus/valgus angulation, however, because of the intact extracapsular tissues and ligaments. With both PCL and posterolateral corner injuries, there is a marked increase in tibia external rotation because of the lack of supporting restraints [36]. Harner et al. demonstrated that the anterolateral component had a greater stiffness and tensile strength than the posteromedial bundle and the meniscofemoral ligaments [12]. Furthermore, Fox et al. demonstrated that at varying degrees of knee flexion, different in situ forces existed. At 0°, the PCL had an average tensile strength of 6.1 N, while at 90°, it had a tensile strength of 112.3 N. The posteromedial bundle attained a maximum force of 67.9 N at 90° of knee flexion, while the anterolateral bundle reached a maximal force of 47.8 N at 60° [37]. Understanding these relationships is critical in reconstructive surgery to ensure that the grafts are tensioned properly.

In addition to its known role in the sagittal plane, the PCL influences knee motion in the frontal plane. This occurs because the PCL inserts onto the lateral aspect of the medial femoral condyle and is oriented obliquely. This orientation of the PCL aids in the articular asymmetry between the medial and lateral femoral condyles and permits adequate tensioning of the PCL during the rolling of the lateral femoral condyle posteriorly in early flexion.

The popliteus muscle aids the PCL in resisting posterior tibial translation and enhancing stability. Harner et al. demonstrated that in a PCL-deficient knee, the popliteus muscle reduced posterior translation of the tibia by 36% [38].
2.3.6 The Interplay of the Cruciate Ligaments

The complex interaction between ACL and PCL at varying degrees of flexion and extension helps account for the dynamic stability of the knee joint. The length and tension of the ACL and the PCL change during flexion and extension owing to their asymmetric insertion sites. In full extension, the ACL is taut, while the PCL is relatively lax. When a person is standing with the knee in hyperextension, the joint is passively stable, with little need for muscular support. As the knee flexes, the posterolateral portion of the ACL becomes lax, while the PCL tightens, especially the anterolateral bundle. Stability is more tenuous between 20 and 50° of flexion since neither cruciate ligament is very taut. The change in the orientation of the ACL and PCL fibers during knee flexion allows for dynamic stability in the sagittal plane. With increasing flexion, the ACL changes from a vertical position to a more horizontal orientation in relation to the joint line. The PCL's orientation is opposite to the ACL's during flexion and extension. Consequently, as the knee reaches higher degrees of flexion, the PCL becomes more important in preventing distraction of the joint [24, 39]. This interplay between ACL and PCL is often referred to as the four-bar cruciate linkage system (Fig. 2.7) [40]. The intersection of these ligaments demonstrates that the center of joint rotation moves posterior with knee flexion. This allows for both sliding and rolling movements of the femur during flexion and prevents the femur from rolling off the tibial plateau at extremes of flexion [2].

During the different phases of the gait cycle, the force vectors about the knee in the sagittal plane change. The mechanical loads across the knee joint are altered by changes in foot position as well as by the intensity and type of ambulatory activity. During normal ambulation, a joint reactive force of two to five times the body weight is produced; this force is up to 24 times the body weight during running. Dynamic muscle forces help to balance these functional loads and joint reactive forces, especially as the knee flexes and the weight-bearing axis shifts from a position anterior to the knee joint to one posterior [41]. If a ligamentous, muscular, and/or bony injury occurs that alters this delicate balance of forces, the joint is not as effective at withstanding these loads, hastening the degenerative process of the knee [24].

The dynamic actions of the surrounding muscles are restrained by the cruciate ligaments during knee flexion and extension. The quadriceps muscles, by way of the patellar tendon, ultimately insert onto the anterior tibia, and, consequently, the tibia is translated anteriorly by the extensor mechanism and constrained by the pull of the ACL. The biomechanical advantage is maximized when the center of rotation of the knee joint is perpendicular to the joint line. If anterior translation occurs in the sagittal plane during ambulation, as with ACL deficiency, the center of rotation is altered, and the resultant increase in forces across the knee joint places increased stress upon the secondary restraints. The moment arm of the knee extensor apparatus is decreased, causing an increase in the muscle forces necessary to maintain balance across the knee joint. This
leads to an increase in joint reactive forces and, ultimately, stressed or injured supporting structures [42]. In an ACL-deficient knee, increased stress is placed on the secondary restraints of anterior translation, including the menisci and the surrounding soft-tissue capsule. When the quadriceps become atrophied after an ACL rupture, the extensor pull on the tibia lessens, decreasing the stresses placed on the secondary stabilizers.

The screw home mechanism again demonstrates the importance of the dynamic muscles in knee motion. As the lateral femoral condyle rolls posteriorly in early flexion, the moment arm of the extensor apparatus increases (Fig. 2.8). This gives a mechanical advantage to the knee in stair climbing and running, when there is maximal demand on the knee joint [39].

2.4 Surgical Implications of Cruciate Anatomy and Biomechanics

2.4.1 The Biomechanics of Ligament Reconstruction

As the incidence of multiple ligament knee injuries increases, the order and necessity of the reconstruction of the ACL, PCL, and the posterolateral corner in combined injuries have become controversial. Harner et al. have demonstrated that in isolated PCL injuries, reconstruction led to an average posterior tibial translation of 1.5 and 2.4 mm at 30 and 90°, respectively. These numbers increased to 6.0 and 4.6 mm if the only PCL was reconstructed in a combined PCL-posterolateral corner injury. In addition, external rotation and varus angulation increased 14 and 7°, respectively. This study supports the reconstruction of both ligaments at the same setting in combined PCL-posterolateral corner injuries [37, 38]. If the ACL is also disrupted, it should be reconstructed either primarily or in a staged procedure, but the PCL and posterolateral corner should be considered to be a higher priority [19]. The specific surgical treatments of ACL- and PCL-based multiple ligament injured knees and treatment approaches are reviewed in following chapters.

2.4.2 Structural Properties of Ligaments and Commonly Used Grafts

The maximal stress that a ligament or graft can withstand prior to failure has been studied extensively. The ACL has been reported to have an average maximal tensile stress to failure of between 1,725 and 2,500 N. Many studies have found the PCL to have significantly more tensile strength than the ACL, but this is controversial [19, 20].

Cooper et al. have shown that the tensile strength of grafts taken from the central third of the patellar tendon averages 4,389 N for grafts 15 mm wide and 2,977 N for grafts 10 mm wide. Twisting the graft 90° increased its strength approximately 30%. This study advocates using 10-mm central-third patellar tendon grafts for ACL reconstruction to avoid the risks of notch impingement and patellar fracture encountered with larger grafts [21]. See Table 2.1 for comparison of mechanical strength of native cruciates and commonly utilized autografts (Table 2.1).
Over time, wear and degeneration cause ligaments and grafts to decrease in strength. This has been demonstrated in multiple studies by means of ACL and graft tensile tests. The biologic effects of aging, maturation, and immobilization may also affect the viscoelastic properties of a ligament or graft, leading to a decrease in biomechanical strength [22].

### 2.4.3 Graft Tensioning

Cruciate anatomy has many surgical implications related to graft tensioning during ACL and PCL reconstruction. High amounts of tension through the graft can result in poor results after surgery due to excessive wear through the tunnels, impaired vascularity, and restricted range of motion [43–49]. Too little tension may result in continued postoperative laxity of the knee. Generally, most surgeons will statically precondition the graft on the back table and/or cyclically precondition the graft in the knee prior to final fixation. Graft tensioning during cruciate reconstruction is also heavily dependent on tunnel placement. The importance of accurate tunnel placement in single- or double-bundle reconstructions or in revision reconstruction situations of the ACL and PCL cannot be understated.

### 2.4.4 Tunnel Placement for Cruciate Reconstruction

Cadaver and computed tomography studies have lead to a different understanding of cruciate ligament anatomy and relationships, osseous landmarks, and anatomical reference points for accurate placement of grafts and tunnels during ACL and PCL reconstructions [6, 15, 16]. The existence of two discrete attachment points of each of the bundles for both the ACL and PCL is now well understood and has brought to focus the surgical implications of reconstructing injured cruciate ligaments anatomically and the resultant functional outcome from surgery.

An abundance of studies have demonstrated the varying effects that tunnel placement and orientation or the addition of a second tunnel has on ACL or PCL graft tension [50–52]. Historically, the most common technical mistake has been to place both femoral and tibial tunnels too far anteriorly. With newer cadaveric and radiologic studies that have clarified the anatomic relationships between the ACL, PCL, and their corresponding bony sites of attachment, the subtleties of accurate tunnel placement during reconstruction are clearer.

Efforts have been made recently to reconstruct both the anterior and PCLs more anatomically utilizing double-bundle techniques and creating multiple tunnels when reconstructing multiple ligament injured knees. These techniques are increasing in use and have been well described [6, 7, 26]. However, drilling of multiple tunnels for double-bundle reconstruction is technically demanding and requires good patient selection and technical skill to avoid complications related to its use. Continued clinical outcome studies are currently underway to further assess the efficacy and safety of anatomic reconstructions of the cruciate ligaments utilizing double-bundle techniques.

### 2.5 Conclusion

Knee dislocations are severe injuries because they may result in disruption of multiple ligaments, surrounding musculature, and neurovascular structures [53]. Diagnosis and acute treatment can be difficult, and the varying techniques that are utilized to reconstruct the anterior and PCLs can be controversial. These injuries, owing to ligamentous disruption and surrounding soft-tissue damage, may lead to a biomechanical disadvantage of the knee joint prior to or after reconstruction attempts are made.
To prevent abnormal translations and angulations in the reconstructed knee, surgeons performing reconstructions in patients with multiple ligament injuries must have a complete understanding of the normal anatomy and biomechanics of the entire knee as well as the anterior and PCLs. This knowledge should help optimize the timing of surgery, the order of ligamentous reconstruction, the anatomic placement of grafts, and the rehabilitation of the surrounding musculature.
