In this chapter we describe the two main methods of meta-analysis, fixed effect model and random effects model, and how to perform the analysis in R. For both models the inverse variance method is introduced for estimation. The pros and cons of these methods in various contexts have been debated at length in the literature [9, 28, 29, 41], without any conclusive resolution. Here, we briefly describe each model, and how it is estimated in the R package meta [33, 34].

An estimated treatment effect and its variance from each study are sufficient to apply the inverse variance method. Therefore, this method is sometimes called the generic inverse variance method. For the random effects model, various methods to estimate the between-study variance, the Hartung–Knapp adjustment and prediction intervals are briefly described.

We also show how to use R to generate forest plots. Along the way, we will show how the tabular and graphical summaries usually included in Cochrane reviews can be generated in R. We give examples using both base R and functions provided by our R package meta. The various methods of meta-analysis are best illustrated using base R; furthermore some basic R knowledge is gained from working with fundamental R functions. The R code using functions from the R package meta shows how routine manipulations and calculations can be automated. In practice a meta-analyst would like to do the analyses using the more sophisticated functions in the R package meta. Accordingly, readers not interested in the mathematical details could run over the examples using base R functions.

We will use a continuous outcome to introduce both fixed effect and random effects model. Accordingly, we start by describing the two most common effect measures for continuous outcomes, mean difference and standardised mean difference.

---

1If you did not already install R package meta do so using R command install.packages("meta").
difference. In Sect. 2.6, the generic inverse variance method is applied in meta-
analyses with survival outcome, cross-over trials and adjusted estimates from
regression models.

2.1 Effect Measures for Continuous Outcomes

Meta-analysis typically focuses on comparing two interventions, which we refer
to as experimental and control. When the response is continuous (i.e. quantitative)
typically the mean, standard deviation and sample size are reported for each group.
Let $\mu_{ek}, s_{ek}^2, n_{ek}$ and $\mu_{ck}, s_{ck}^2, n_{ck}$ denote the observed mean, standard deviation and
sample size for study $k, k = 1, \ldots, K$ (see Table 2.1).

We consider two different types of effect measures for continuous outcomes:
mean difference and standardised mean difference. The mean difference is typically
used when all studies report the outcome on the same scale. On the other hand,
the standardised mean difference can be used when studies measure the outcome on
different scales, e.g. different depression scales like the Hamilton Depression Rating
Scale or the Hospital Anxiety and Depression Scale.

2.1.1 Mean Difference

For study $k$, the estimated mean difference is

$$\hat{\mu}_k = \hat{\mu}_{ek} - \hat{\mu}_{ck},$$

(2.1)

with variance estimate
\[ \text{Var}(\hat{\mu}_k) = \frac{s^2_{ek}}{n_{ek}} + \frac{s^2_{ck}}{n_{ck}}. \] (2.2)

An approximate two-sided \((1 - \alpha)\) confidence interval for the mean difference is given by
\[ (\hat{\mu}_{ek} - \hat{\mu}_{ck}) \pm z_{1-\frac{\alpha}{2}} \sqrt{\frac{s^2_{ek}}{n_{ek}} + \frac{s^2_{ck}}{n_{ck}}} \] (2.3)
with \(z_{1-\frac{\alpha}{2}}\) denoting the \(1 - \frac{\alpha}{2}\) quantile of the standard normal distribution. For the usual 95\% confidence interval, \(z_{1-\frac{0.05}{2}} = z_{0.975} = 1.96\), i.e. the 97.5\% point of the standard normal distribution.

**Example 2.1** We return to the meta-analysis by Spooner et al. [37] comparing Nedocromil sodium with placebo for preventing exercise-induced bronchoconstriction which we already used in Chap. 1. Outcome of interest is the maximum fall in the forced expiratory volume in 1 second (FEV\(_1\)) over the course of follow-up, expressed as a percentage. Accordingly, all studies report the same outcome and the use of the mean difference is warranted.

The raw data consist of eight variables with headings in Table 2.1. Code to read in the data, together with the data, are shown in Fig. 1.2. From the data we see that the meta-analysis contains 17 studies, with sample sizes ranging between 16 (Shaw 1985; DeBenedictis 1995) and 48 (Novembre 1994f).

For each study (labelled by first author and date) mean values, standard deviations and sample sizes are given in Fig. 1.2. Thus for study 1 (Boner 1988) the estimated mean difference is \(13.54 - 20.77 = -7.23\) and for study 2 (Boner 1989) it is \(15.70 - 22.70 = -7.00\) (see Fig. 1.4). Accordingly, the maximum fall in FEV\(_1\) is on average about 7\% in Boner 1988 and Boner 1989. For study 1 (Boner 1988) the 95\% confidence interval (2.3) is
\[ (13.54 - 20.77) \pm 1.96 \sqrt{\frac{13.85^2}{13} + \frac{21.46^2}{13}} \text{ giving } (-21.11, 6.65). \]

We can use base R to calculate mean difference and 95\% confidence interval for the Boner 1988 trial (assuming that the file dataset01.csv is in the current working directory; see Sect. 1.2 for details):

```r
> # 1. Read in the data
> data1 <- read.csv("dataset01.csv", as.is=TRUE)
> # 2. Calculate mean difference and its standard error for
```

\(^2\)Note we could use a pooled estimate of the sample variance, but this assumes that the response variance is the same in the two groups which will not be true in general.
> # study 1 (Boner 1988) of dataset data1:
> MD <- with(data1[1,, Me - Mc)
> seMD <- with(data1[1,, sqrt(Se^2/Ne + Sc^2/Nc))
> # 3. Print mean difference and limits of 95% confidence interval using round function to show only two digits:
> round(c(MD, MD + c(-1,1) * qnorm(1-(0.05/2)) * seMD), 2)

The values for mean difference, lower and upper limit of the 95% confidence interval are identical to those calculated manually.

We can also use the metacont function from R package meta to calculate mean difference and confidence interval:

> print(metacont(Ne, Me, Se, Nc, Mc, Sc),
+ data=data1, subset=1, digits=2)

<table>
<thead>
<tr>
<th>MD</th>
<th>95%-CI</th>
<th>z</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>-7.23</td>
<td>[-21.11; 6.65]</td>
<td>-1.02</td>
<td>0.3074</td>
</tr>
</tbody>
</table>

Details:
- Inverse variance method

We get the same result by using the metacont function with argument sm="MD" (i.e. summary measure is the Mean Difference) as this is the default setting.

Note, the printout states that the inverse variance method has been used which strictly speaking refers to the method of meta-analysis, i.e. a setting with at least two studies. For a single study this simply means that Eqs. (2.1)–(2.3) have been used in the calculation of the mean difference and its confidence interval.

Instead of using the with function, a more convenient way is to use the metacont function with arguments data and subset.

> print(metacont(Ne, Me, Se, Nc, Mc, Sc,
+ data=data1, subset=1), digits=2)

<table>
<thead>
<tr>
<th>MD</th>
<th>95%-CI</th>
<th>z</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>-7.23</td>
<td>[-21.11; 6.65]</td>
<td>-1.02</td>
<td>0.3074</td>
</tr>
</tbody>
</table>

*** Output truncated ***

In addition to mean difference and its 95% confidence interval, the metacont function reports z-score and p-value for the test of an overall treatment effect. These quantities can be calculated using base R functions pnorm and abs as follows:

> zscore <- MD/seMD
> round(c(zscore, 2*pnorm(abs(zscore), lower.tail=FALSE), [1] -1.0206 0.3074

When calling metacont we are matching up the first argument n.e of the metacont function with the variable Ne of the Boner 1988 trial; and similarly for the other arguments. In order to access the data of the Boner 1988 trial we use the argument subset=1 which selects the first row of the dataset data1. A more
general way to select the Boner 1988 trial which is not relying on the order of the dataset is `subset=(author=="Boner"&year=="1988").3

The argument `subset` can also be used to exclude some studies, e.g., `subset=-2` selects all but the second trial, `subset=author!="Boner"` excludes all trials from the author Boner, and `subset=! (author=="Boner" &year=="1988")` excludes the Boner 1988 trial.4

2.1.2 Standardised Mean Difference

In the bronchoconstriction meta-analysis used in Example 2.1 all studies measured the outcome of interest on the same scale, so an overall effect can be estimated directly by pooling the mean differences in the individual studies. However, in many settings different studies use different outcome scales, e.g. different depression scales or quality of life scales. In such cases we cannot pool the effect estimates (mean differences) directly. Instead, we calculate a dimensionless effect measure from every study and use this for pooling. A very popular dimensionless effect measure is the standardised mean difference which is the study’s mean difference divided by a standard deviation based either on a single treatment group or both treatment groups.

There are a number of formulae in the literature for calculating a standardised mean difference and its variance; see Chapter 16 of Cooper and Hedges [3] for a summary. The `metacont` function from R package `meta` uses the same estimator as RevMan 5 [40], i.e. a version of the standardised mean difference which is called Hedges’s `g` [15, 16] based on the pooled sample variance. This standardised mean difference for study `k` is calculated as:

\[
\hat{g}_k = \left(1 - \frac{3}{4n_k - 9}\right) \frac{\hat{\mu}_{ek} - \hat{\mu}_{ek}}{\sqrt{(n_{ek} - 1)s_{ek}^2 + (n_{ck} - 1)s_{ck}^2} / (n_k - 2)}
\]

(2.4)

where `n_k = n_{ek} + n_{ck}` and the factor `1 - 3/(4n_k - 9)` corrects for the bias in the estimated standard error. To calculate a confidence interval for `\hat{g}_k`, we need its variance; again following RevMan 5 this is calculated as [18, page 80, equation (8)]

\[
\hat{\text{Var}}(\hat{g}_k) = \frac{n_k}{n_{ek} \cdot n_{ck}} + \frac{\hat{g}_k^2}{2(n_k - 3.94)}.
\]

(2.5)

3The parentheses are not mandatory to select Boner 1988; we use them only to make the R code more accessible.

4The parentheses are mandatory to exclude Boner 1988 using the variables `author` and `year`.
Once $\hat{g}_k$ and $\text{Var}(\hat{g}_k)$ are calculated a two-sided $(1-\alpha)$ confidence interval can be calculated by

$$\hat{g}_k \pm z_{1-\frac{\alpha}{2}} \text{S.E.}(\hat{g}_k)$$

with standard error $\text{S.E.}(\hat{g}_k) = \sqrt{\text{Var}(\hat{g}_k)}$ and $z_{1-\frac{\alpha}{2}}$ denoting the $1-\frac{\alpha}{2}$ quantile of the standard normal distribution.

**Example 2.2** Furukawa et al. [10] carried out a systematic review comparing low dosage tricyclic antidepressants with placebo for the treatment of depression. They reported the effect on presence/absence of depression and on depression severity. Here we focus on the latter outcome. Unfortunately, different studies used different scores to measure depression severity, e.g., 19 studies used some version of the Hamilton Depression Rating Scale and five studies used the Montgomery-Åsberg Depression Rating Scale. Accordingly, it is not possible to pool the estimated effects directly.

Figure 2.1 reads in and views the data assuming that the file `dataset02.csv` is in the current working directory; see Sect. 1.2 for details. The large differences in means (columns $\text{Me}$, $\text{Mc}$) and standard deviations (columns $\text{Se}$, $\text{Sc}$) within the experimental and control arms are typical of what occurs when different studies use different outcome measures.

For each study (labelled by first author) mean values, standard deviations and sample sizes are given in Fig. 2.1. For study 1 (Blashki), the standardised mean difference with its 95% confidence interval can be calculated using formulae (2.4) to (2.6) in the following way:

$$\hat{g}_1 = \left(1 - \frac{3}{4(13 + 18) - 9}\right) \cdot \frac{6.4 - 11.4}{\sqrt{(12 \cdot 5.4^2 + 17 \cdot 9.6^2)/(13 + 18 - 2)}} = -0.60.$$  

Further

$$\text{Var}(\hat{g}_1) = \frac{13 + 18}{13 \cdot 18} + \frac{-0.60^2}{2(13 + 18 - 3.94)} = 0.1391305$$

and thus

$$\text{S.E.}(\hat{g}_1) = \sqrt{0.1391305} = 0.373002.$$  

The 95% confidence interval is

$$-0.6 \pm 1.96 \cdot 0.373002, \quad \text{i.e.} \quad (-1.33, 0.13).$$

Fig. 2.1 Data from meta analysis by Furukawa et al. [10]. See Table 2.1 for details on the variables in dataset data2

We can calculate the standardised mean difference, its standard error and 95% confidence interval for study 1 (Blashki) using base R:

> # 1. Calculate standardised mean difference (SMD) and
> # its standard error (seSMD) for study 1 (Blashki) of
> # dataset data2:
> N <- with(data2[1,], Ne + Nc)
> SMD <- with(data2[1,],
+ (1 - 3/(4 * N - 9)) * (Me - Mc) /
+ sqrt(((Ne - 1) * Se^2 + (Nc - 1) * Sc^2)/(N - 2)))
> seSMD <- with(data2[1,],
+ sqrt(N/(Ne * Nc) + SMD^2/(2 * (N - 3.94))))
> # 2. Print standardised mean difference and limits of 95% CI
> # interval using round function to show only two digits:
> round(c(SMD, SMD + c(-1,1) * qnorm(1-(0.05/2)) * seSMD), 2)
[1] -0.60 -1.33  0.13
We get the same result by using the `metacont` function with argument `sm="SMD"` (Standardised Mean Difference):

```r
> print(metacont(Ne, Me, Se, Nc, Mc, Sc, sm="SMD",
+ data=data2, subset=1), digits=2)
SMD 95%-CI z p-value
-0.6 [-1.33; 0.13] -1.61 0.1083
```

Details:
- Inverse variance method

Once the standardised mean difference and its variance have been calculated using the formulae (2.4) and (2.5), the calculations for both fixed effect and random effects meta-analyses follow exactly as described in the next section.

### 2.2 Fixed Effect Model

The fixed effect model assumes that the estimated effects from the component studies in a meta-analysis come from a single homogeneous population. In order to calculate an overall estimate, we therefore average the estimates from each study, allowing for the fact that some estimates are more precise than others (having come from larger studies).

More formally, let $k = 1, \ldots, K$ index study, $\hat{\theta}_k$ denote the intervention effect estimate from study $k$, and $\theta$ denote the intervention effect in the population, which we wish to estimate. Denote by $\hat{\sigma}_k^2$ the sample estimate of $\text{Var}(\hat{\theta}_k)$.

The fixed effect model is

$$
\hat{\theta}_k = \theta + \alpha_k \epsilon_k, \quad \epsilon_k \sim \text{i.i.d.} N(0, 1). \tag{2.7}
$$

We now consider the fixed effect estimate of $\theta$, denoted by $\hat{\theta}_F$. Given estimates $(\hat{\theta}_k, \hat{\sigma}_k), k = 1, \ldots, K$, the maximum-likelihood estimate under model (2.7) is

$$
\hat{\theta}_F = \frac{\sum_{k=1}^{K} \hat{\theta}_k / \hat{\sigma}_k^2}{\sum_{k=1}^{K} 1 / \hat{\sigma}_k^2} = \frac{\sum_{k=1}^{K} w_k \hat{\theta}_k}{\sum_{k=1}^{K} w_k}. \tag{2.8}
$$

Accordingly, $\hat{\theta}_F$ is a weighted average of the individual effect estimates $\hat{\theta}_k$ with weights $w_k = 1 / \hat{\sigma}_k^2$. Therefore, this method is called the inverse variance method.

The variance of $\hat{\theta}_F$ is estimated by

$$
\hat{\text{Var}}(\hat{\theta}_F) = \frac{1}{\sum_{k=1}^{K} w_k}. \tag{2.9}
$$
A (1 - α) confidence interval for \( \hat{\theta}_F \) can be calculated by

\[
\hat{\theta}_F \pm z_{1-\frac{\alpha}{2}} \text{ S.E.}(\hat{\theta}_F)
\]  

(2.10)

with standard error \( \text{S.E.}(\hat{\theta}_F) = \sqrt{\text{Var}(\hat{\theta}_F)} \) and \( z_{1-\frac{\alpha}{2}} \) denoting the \( 1 - \frac{\alpha}{2} \) quantile of the standard normal distribution. A corresponding test for an overall treatment effect can be constructed using \( \hat{\theta}_F / \text{S.E.}(\hat{\theta}_F) \) as test statistic.

**Example 2.3** The fixed effect estimate \( \hat{\theta}_F \) and its 95% confidence interval for the bronchoconstriction meta-analysis are given in Fig. 1.4; here we show how \( \hat{\theta}_F \) can be calculated using R. Recall Eqs. (2.1) and (2.2) which give the mean difference \( \hat{\mu}_k \) and its variance estimate \( \text{Var}(\hat{\mu}_k) \). The fixed effect estimate \( \hat{\theta}_F \) and its variance can be calculated using the following quantities:

\[
\hat{\theta}_k = \hat{\mu}_k \\
\hat{\sigma}_k^2 = \sqrt{\text{Var}(\hat{\mu}_k)}.
\]

The fixed effect estimate and its variance can be calculated using base R code:

```r
> # 1. Calculate mean difference, variance and weights
> MD <- with(data1, Me - Mc)
> varMD <- with(data1, Se^2/Ne + Sc^2/Nc)
> weight <- 1/varMD
> # 2. Calculate the inverse variance estimator
> round(weighted.mean(MD, weight), 4)
[1] -15.514
> # 3. Calculate the variance
> round(1/sum(weight), 4)
[1] 1.4126
```

Note, the standard `weighted.mean` function is used to calculate \( \hat{\theta}_F \).

The meta-analysis can be conducted much easier using the `metacont` function which yields identical results:

```r
> mcl <- metacont(Ne, Me, Se, Nc, Mc, Sc,
+ data=data1,
+ studlab=paste(author, year))
> round(c(mcl$TE.fixed, mcl$seTE.fixed^2), 4)
```

We select `mcl$TE.fixed`, i.e. the Treatment Estimate in the fixed effect model, and its standard error `mcl$seTE.fixed` from the meta-analysis object `mcl`. We can use the command `str(mcl)` to print the whole structure of the meta-analysis object `mcl` and look at the help page of the `metacont` function which describes the individual elements of `mcl`.

A complete printout for the meta-analysis is given in Fig. 2.2. The first thing the output gives is a table whose rows are the component studies in the meta-analysis.

Details on meta-analytical method:
- Inverse variance method
- DerSimonian-Laird estimator for \( \tau^2 \)

Fig. 2.2 Output from meta-analysis of the bronchoconstriction meta-analysis [37]. The output starts with a table of the included studies. For each study, the mean difference (MD) with 95% confidence interval is given, along with weights used for fixed effect and random effects model. There are 17 studies in the example. Next, the results of fixed effect and random effects model are presented with 95% confidence intervals, \( z \) statistic and \( p \)-value. Heterogeneity is quantified by the estimated between-study variance \( \tau^2 \), \( H \) and \( I^2 \), see Sects. 2.3 and 2.4, and tested using Cochran’s \( Q \) statistic, see Eq. (2.12). There is not much heterogeneity present in this example. The output ends with details of the methods used, e.g. how \( \tau^2 \) was estimated, see Sect. 2.3.1

This table is also shown in Fig. 1.4 on the right side of the forest plot. The column MD is the mean difference of the response (maximum change in FEV₁ as a percentage) between the Nedocromil sodium and placebo group. Next comes a 95% confidence interval for this difference, calculated based on (2.3). The next two columns are the
weights given to the study under the fixed effect ($\%W_{\text{fixed}}$) and random effects model ($\%W_{\text{random}}$).

The weight of study 1 (Boner 1988) in the fixed effect meta-analysis is given by the inverse of the variance (2.2) which can be calculated as

$$\frac{1}{\left( \frac{13.85^2}{13} + \frac{21.46^2}{13} \right)} = \frac{1}{50.18108} = 0.01992783.$$  

The percentage weight of study 1 (Boner 1988) in the fixed effect meta-analysis reported in Figs. 1.4 and 2.2 is

$$100 \cdot \frac{w_1}{\sum_{i=1}^{12} w_i} = 100 \cdot \frac{0.01992783}{0.7079028} = 2.82 \%.$$  

We could also use R to calculate these values:

```r
> mc1$w.fixed[1]
[1] 0.01992783
> sum(mc1$w.fixed)
[1] 0.7079028
> round(100*mc1$w.fixed[1] / sum(mc1$w.fixed), 2)
[1] 2.82
```

After reporting the number of studies combined in meta-analysis, fixed effect estimate $\hat{\theta}_F$, random effects estimate $\hat{\theta}_R$ (see Sect. 2.3) and their 95% confidence intervals, $z$ and $p$-values are given in Fig. 2.2. Next come the measures for heterogeneity and a test for heterogeneity (see Sect. 2.4). Finally a note indicates that the “Inverse variance method” has been used. This is in fact the only method for continuous data; but with binary data (see Chap. 3) we shall see there are other alternatives.

A forest plot is shown in Fig. 2.3 which has been produced by the R command

```r
> forest(mc1, comb.random=FALSE, xlab="Difference in mean response (intervention - control) units: maximum % fall in FEV1",
+ xlim=c(-50,10), xlab.pos=-20, smlab.pos=-20)
```

Note the use of the `xlab` option to label the x-axis, and in particular how a line break in the input text creates a line break in the axis label on the graph. The option `xlim=c(-50,10)` is used to specify that the limits of the x-axis are between $-50$ and $10$. The options `xlab.pos` and `smlab.pos` specify the centre of the label on x-axis and the summary measure at the top of the figure; otherwise these texts would be centred around 0.

Note, the meta-analysis could have also been done using the `metagen` function which is the primary function in R package `meta` to conduct a meta-analysis based on the generic inverse variance method.

```r
> # 1. Apply generic inverse variance method
> mcl.gen <- metagen(mcl$TE, mcl$seTE, sm="MD")
```

**Fig. 2.3** Forest plot for the bronchoconstriction meta-analysis [37]. For details, see text.

```r
> # 2. Same result
> mcl.gen <- metagen(TE, seTE, data=mcl, sm="MD")
> # 3. Print results for fixed effect and random effects method
> c(mcl$TE.fixed, mcl$TE.random)
> c(mcl.gen$TE.fixed, mcl.gen$TE.random)
```

In steps 1 and 2, the generic inverse variance method is applied using the `metagen` function; we use the list elements `mcl$TE` (treatment effect) and `mcl$seTE` (standard error) as inputs to the `metagen` function. Output of resulting object `mcl.gen` is identical to results using the `metacont` function as exemplified in step 3 for the fixed effect and random effects estimates. Applying the `metagen` function in this way seems rather artificial, however, as we will see in Sect. 2.6 this function can be used to conduct a meta-analysis for other outcomes.

Following RevMan 5, the following quantities are used to estimate the standardised mean difference in the fixed effect model:

\[
\hat{\theta}_k = \hat{g}_k \\
\hat{\sigma}_k^2 = \hat{\text{Var}}(\hat{g}_k)
\]

with \( \hat{g}_k \) and \( \hat{\text{Var}}(\hat{g}_k) \) defined in (2.4) and (2.5). These quantities are utilised in formulae (2.8)–(2.10) to calculate the fixed effect estimate of the standardised mean difference.
Example 2.4  For the standardised mean difference, we can calculate the fixed effect estimate and its variance using base R:

```r
> # 1. Calculate standardised mean difference, 
> # variance and weights 
> N <- with(data2, Ne + Nc) 
> SMD <- with(data2, 
+ (1 - 3/(4 * N - 9)) * (Me - Mc)/ 
+ sqrt(((Ne - 1) * Se^2 + (Nc - 1) * Sc^2)/(N - 2))) 
> varSMD <- with(data2, 
+ N/(Ne * Nc) + SMD^2/(2 * (N - 3.94))) 
> weight <- 1/varSMD 
> # 2. Calculate the inverse variance estimator 
> round(weighted.mean(SMD, weight), 4) 
[1] -0.3915 
> # 3. Calculate the variance 
> round(1/sum(weight), 4) 
[1] 0.0049 
```

Again, the meta-analysis can be conducted using the `metacont` function:

```r
> mc2 <- metacont(Ne, Me, Se, Nc, Mc, Sc, sm="SMD", data=data2) 
> round(c(mc2$TE.fixed, mc2$seTE.fixed^2), 4) 
[1] -0.3915 0.0049 
```

A complete summary for the meta-analysis is given in Fig. 2.4.

```r
> print(summary(mc2), digits=2) 
Number of studies combined: k=17

       SMD   95%-CI       z    p-value
Fixed effect model -0.39 [-0.53; -0.25] -5.61 < 0.0001
Random effects model -0.59 [-0.87; -0.30] -4.04 < 0.0001

Quantifying heterogeneity:
  tau^2 = 0.2309; H = 1.91 [1.5; 2.43]; I^2 = 72.5% [55.4%; 83.1%]

Test of heterogeneity:
  Q d.f.   p-value
  58.27    16 < 0.0001

Details on meta-analytical method:
  - Inverse variance method
  - DerSimonian-Laird estimator for tau^2
```

Fig. 2.4  Output from meta-analysis of the tricyclic antidepressants for depression [10]. The output is organised similar to Fig. 2.2, except that information on individual studies is omitted by using the `summary.meta` function.
2.3 Random Effects Model

The random effects model seeks to account for the fact that the study effect estimates $\hat{\theta}_k$ are often more variable than assumed in the fixed effect model. Under the random effects model,

$$\hat{\theta}_k = \theta + u_k + \sigma_k \epsilon_k, \quad \epsilon_k \sim \text{i.i.d. } N(0, 1); \quad u_k \sim N(0, \tau^2), \quad (2.11)$$

where the $u$’s and $\epsilon$’s are independent. Comparing with (2.7) shows the random effects model has the fixed effect model as a special case when $\tau^2 = 0$. A key assumption of the random effects model is that the $u_k$ we see in our data are not intrinsically associated with study $k$; if study $k$ was rerun, the new $u_k$ would be an independent draw from $N(0, \tau^2)$. This is known as the exchangeability assumption. If we accept this assumption then, compared with the fixed effect model, calculating an overall effect estimate will pay greater attention to the effect estimates from the smaller studies. This difference with the fixed effect model lies at the heart of discussions about whether the random effects model is appropriate. A number of authors have argued that, as small studies are more susceptible to bias, the fixed effect estimate is (almost) always preferable [11, 30].

Under the random effects model there are a number of options for estimating $\tau^2$, $\text{Var}(\hat{\theta})$ and $\tau^2$. Maximum-likelihood is attractive, but the resulting variance estimates are biased downwards if the number of studies is small. This has led to the widespread use of the method of moments estimate proposed by DerSimonian and Laird [7], which has the attraction that it can be readily calculated when the response is discrete, when maximum-likelihood estimation is less straightforward.

Again, the default settings in the metacont function are the same as those in RevMan 5. Define

$$Q = \sum_{k=1}^{K} w_k (\hat{\theta}_k - \hat{\theta}_F)^2 \quad (2.12)$$

the weighted sum of squares about the fixed effect estimate with $w_k = 1/\hat{\sigma}_k^2$. This is usually referred to as either the homogeneity test statistic or the heterogeneity statistic [18, p. 266, 290]. Next define

$$S = \sum_{k=1}^{K} w_k - \frac{\sum_{k=1}^{K} w_k^2}{\sum_{k=1}^{K} w_k}.$$

If $Q < (K - 1)$, then $\hat{\tau}^2$ is set to 0 and the random effects estimate $\hat{\theta}_R$ is set equal to the fixed effect estimate $\hat{\theta}_F$. Otherwise, the DerSimonian–Laird estimator of the
between-study variance is defined as

\[ \hat{\tau}^2 = \frac{Q - (K - 1)}{S} \]

and the random effects estimate and its variance are given by

\[ \hat{\theta}_R = \frac{\sum_{k=1}^{K} w_k^* \hat{\theta}_k}{\sum_{k=1}^{K} w_k^*} \]

\[ \hat{\text{Var}}(\hat{\theta}_R) = \frac{1}{\sum_{k=1}^{K} w_k^*} \]

(2.13) (2.14)

with weights \( w_k^* = 1/ (\hat{\sigma}_k^2 + \hat{\tau}^2) \). The random effects estimator \( \hat{\theta}_R \) is a weighted average of the individual effect estimates \( \hat{\theta}_k \) with weights \( 1/ (\hat{\sigma}_k^2 + \hat{\tau}^2) \). Accordingly, this method is often called “Inverse variance method”, too.

A \( (1-\alpha) \) confidence interval for \( \hat{\theta}_R \) can be calculated by

\[ \hat{\theta}_R \pm z_{1-\frac{\alpha}{2}} \text{S.E.}(\hat{\theta}_R) \]

(2.15)

with standard error \( \text{S.E.}(\hat{\theta}_R) = \sqrt{\hat{\text{Var}}(\hat{\theta}_R)} \) and \( z_{1-\frac{\alpha}{2}} \) denoting the \( 1 - \frac{\alpha}{2} \) quantile of the standard normal distribution. A corresponding test for an overall treatment effect can be constructed using \( \hat{\theta}_R / \text{S.E.}(\hat{\theta}_R) \) as test statistic.

Note, formulae (2.13)–(2.15) are used for the standardised mean difference, too.

The method used to estimate the between-study variance \( \tau^2 \) may have a large impact on the weighting of studies. Several methods to estimate \( \tau^2 \) besides the DerSimonian–Laird method have been published in the literature. These methods will be described in the next Sect. 2.3.1.

Example 2.5 The result for the random effects model fitted to the bronchoconstriction dataset is given in Fig. 2.2. The weight of study 1 (Boner 1988) is

\[ 100 \cdot \frac{w_1^*}{\sum_{i=1}^{K} w_i^*} = 100 \cdot \frac{0.019005}{0.6179183} = 3.08. \]

The random effects estimate is very similar to the fixed effect estimate \( \hat{\theta}_F = -15.5, \hat{\theta}_R = -15.6 \); likewise confidence interval limits are similar.

Example 2.6 For the depression meta-analysis fixed effect and random effects estimates are rather different \( \hat{\theta}_F = -0.39, \hat{\theta}_R = -0.59 \), see Fig. 2.4. Furthermore, the confidence interval for the random effects model is much wider. Nevertheless,
both models show a highly statistically significant beneficial effect of tricyclic antidepressants on depression severity.

\[ \square \]

2.3.1 Estimation of Between-Study Variance

The following methods to estimate the between-study variance \( \tau^2 \) are available in the \texttt{metagen} and other functions of R package \texttt{meta} (argument \texttt{method.tau}): 

- DerSimonian–Laird estimator [7] (\texttt{method.tau="DL"}) (default)
- Paule–Mandel estimator [27] (\texttt{method.tau="PM"})
- Restricted maximum-likelihood estimator [43] (\texttt{method.tau="REML"})
- Maximum-likelihood estimator [43] (\texttt{method.tau="ML"})
- Hunter–Schmidt estimator [22, 43] (\texttt{method.tau="HS"})
- Sidik–Jonkman estimator [35] (\texttt{method.tau="SJ"})
- Hedges estimator [17] (\texttt{method.tau="HE"})
- Empirical Bayes estimator [39] (\texttt{method.tau="EB"}).

The DerSimonian–Laird estimator is by far the most popular method, especially in medical research. For example, the Der Simonian–Laird estimator is the only method available in RevMan 5 [40]. Accordingly, this method is the default in R package \texttt{meta}.

The properties of these estimators have been evaluated in Monte Carlo simulations [36, 43] as well as analytically [43]. Results of these evaluations are inconsistent, recommending the restricted maximum-likelihood estimator [43] and Sidik–Jonkman or Empirical Bayes estimator [36], respectively.

As a technical note, with exception of the DerSimonian–Laird and the Paule–Mandel methods the \texttt{rma.uni} function of R package \texttt{metafor} is called internally in the \texttt{metagen} function. Thus, it is a good idea to install R package \texttt{metafor} to make all estimation methods available.\footnote{R command: \texttt{install.packages("metafor")}.} Further details on the various methods are provided in the help page of the \texttt{rma.uni} function.

\textbf{Example 2.7} A forest plot with results for the various estimates of \( \tau^2 \) in the bronchoconstriction dataset is shown in Fig. 2.5.\footnote{R code to create the forest plot is given in the web-appendix.} Results are similar for DerSimonian–Laird, restricted maximum-likelihood and empirical Bayes estimator. Whereas the Sidik–Jonkman estimator is surprisingly large, other estimators (i.e. Paule–Mandel, maximum-likelihood, Hunter–Schmidt and Hedges) are rather small. The very large estimate of \( \tau^2 \) from the Sidik–Jonkman method cautions against relying exclusively on this approach.\footnote{\texttt{R} command: \texttt{install.packages("metafor")}.}

Fig. 2.5 Forest plot for the bronchoconstriction meta-analysis [37] comparing estimation methods for between-study heterogeneity $\tau^2$

2.3.2 Hartung–Knapp Adjustment

Hartung and Knapp [14, 25] introduced a new meta-analysis method based on a refined variance estimator in the random effects model. It has been argued in a recent publication in the Annals of Internal Medicine that the Hartung–Knapp method is preferred over the DerSimonian–Laird method [4].

Instead of using the variance estimate given in Eq. (2.14), Hartung and Knapp propose to use the following variance estimator for $\hat{\theta}_R$:

$$\hat{\text{Var}}_{\text{HK}}(\hat{\theta}_R) = \frac{1}{K-1} \sum_{k=1}^{K} \frac{w_k^*}{w^*} \left( \hat{\theta}_k - \hat{\theta}_R \right)^2$$

(2.16)

with weights $w_k^*$ as given in Eq. (2.14) and $w^* = \sum_{k=1}^{K} w_k^*$.

Hartung [13] showed that

$$\frac{\hat{\theta}_R - \theta}{\text{S.E.}_{\text{HK}}(\hat{\theta}_R)}$$

with standard error $\text{S.E.}_{\text{HK}}(\hat{\theta}_R) = \sqrt{\hat{\text{Var}}_{\text{HK}}(\hat{\theta}_R)}$ follows a $t$-distribution with $K - 1$ degrees of freedom.

Accordingly, a $(1-\alpha)$ confidence interval for $\hat{\theta}_R$ based on the Hartung–Knapp method can be calculated by

$$\hat{\theta}_R \pm t_{K-1;1-\frac{\alpha}{2}} \text{S.E.}_{\text{HK}}(\hat{\theta}_R)$$

(2.17)
with $t_{K-1;1-\frac{q}{2}}$ denoting the $1 - \frac{q}{2}$ quantile of the $t$-distribution with $K - 1$ degrees of freedom. A corresponding test for an overall treatment effect can be constructed using $\hat{\theta}_R / \text{S.E.}_{HK}(\hat{\theta}_R)$ as test statistic.

It has been shown in simulations [25] that a test based on the Hartung–Knapp modification holds the prespecified significance level much better than tests based on $\text{S.E.}(\hat{\theta}_F)$ and $\text{S.E.}(\hat{\theta}_R)$.

**Example 2.8** Results of fixed effect and random effects model to evaluate the use of tricyclic antidepressants for depression [10] are reported in Fig. 2.4.

We can either use the `metacont` function to conduct the Hartung–Knapp adjustment

```r
> mc2.hk <- metacont(Ne, Me, Se, Nc, Mc, Sc, sm="SMD",
+ data=data2, comb.fixed=FALSE,
+ hakn=TRUE)
```

or the `metagen` function

```r
> mc2.hk <- metagen(TE, seTE, data=mc2, comb.fixed=FALSE,
+ hakn=TRUE)
```

We print the summary of the meta-analysis in the usual way.

```r
> print(summary(mc2.hk), digits=2)
Number of studies combined: k=17

<table>
<thead>
<tr>
<th>95%-CI</th>
<th>t</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>-0.59 [-1.22]</td>
<td>-3.4</td>
<td>0.0036</td>
</tr>
</tbody>
</table>

Quantifying heterogeneity:

- $\tau^2 = 0.2309$; $H = 1.91 [1.5; 2.43]$; $I^2 = 72.5\% [55.4\%; 83.1\%]$

Test of heterogeneity:

- $Q$ d.f. p-value
- 58.27 16 < 0.0001

Details on meta-analytical method:

- Inverse variance method
- DerSimonian-Laird estimator for $\tau^2$
- Hartung-Knapp adjustment for random effects model

Use of the Hartung–Knapp method yields a much wider 95% confidence interval as compared to the classic random effects model (see Fig. 2.4): $[-0.95; -0.22]$ versus $[-0.87; -0.30]$. Furthermore, using the test for an overall treatment effect is based on a $t$-distribution with $K - 1$ degrees of freedom. Accordingly, the $p$-value is much larger ($p = 0.0036$) as compared to the $p$-value of the classic random effects method ($p < 0.0001$, see Fig. 2.4). Nonetheless, the test for an overall treatment effect is still highly significant.
2.3.3 Prediction Intervals

The confidence interval for the random effects estimator \( \hat{\theta}_R \) given by Eq. (2.15) describes the uncertainty in the estimation of the mean treatment effect. However, in order to calculate a prediction interval \([21]\) for the treatment effect in a future study from the random effects model (2.11), we need to take into account not only uncertainty in estimating the mean treatment effect but also the between-study variance \( \tau^2 \).

Such a \((1 - \alpha)\) prediction interval can be calculated as

\[
\hat{\theta}_R \pm t_{K-2,1-\frac{\alpha}{2}} \sqrt{\hat{\text{Var}}(\hat{\theta}_R) + \tau^2},
\]

where we include the estimate of \( \tau \) in the variance, and \( t_{K-2,1-\frac{\alpha}{2}} \) denotes the \( 1 - \frac{\alpha}{2} \) quantile of the \( t \)-distribution with \( K - 2 \) degrees of freedom.

Example 2.9 In the R package meta a prediction interval can be printed in several ways. We can use the argument \texttt{prediction=TRUE} in the creation of a meta-analysis object using the \texttt{metacont} function.\(^7\) Or, we can specify the prediction argument in a \texttt{summary}, \texttt{forest} or \texttt{print} command. In the following R code we use the \texttt{prediction} argument in the \texttt{summary.meta} command.

```r
> print(summary(mc1, prediction=TRUE), digits=2)
Number of studies combined: k=17

Fixed effect model    -15.51 [-17.84; -13.18]  -13.05 < 0.0001
Random effects model  -15.64 [-18.14; -13.15]  -12.30 < 0.0001
Prediction interval    [-19.94; -11.35]

*** Output truncated ***
```

The result for the prediction interval is printed just below the results for the two meta-analysis methods. Note that the point estimate, i.e. the random effects estimate \( \hat{\theta}_R \), is not reported for a prediction interval. In the bronchoconstriction meta-analysis the prediction interval is \((-19.94; -11.35)\). Therefore, in a new study we expect an average treatment effect of more than 11%.

A forest plot showing a prediction interval can be easily generated using the following command:

```r
> forest(mc1, prediction=TRUE, col.predict="black")
```

This is shown in Fig. 2.6. The prediction interval is shown as a bar below the two diamonds for the meta-analysis results. We changed the colour of the bar to black; by default, a red bar would be printed.

\(^7\)We did not do this in the creation of R object mc1.
### 2.4 Tests and Measures of Heterogeneity

There are a number of heterogeneity measures in the literature [19, 32]. The most commonly used measures are calculated by the metacont function, and we now briefly describe them. More details on these measures are given in Sect. 4.2.

The first, $Q$, defined in (2.12), is the weighted sum of squares about the fixed effect estimate $\hat{Q}$. Large values of $Q$ indicate greater heterogeneity between the individual studies in a meta-analysis, and greater values of the between-study heterogeneity $/FS2$. Under the null hypothesis that $/FS2 = 0$, $Q$ has mean $/FS2$, so $H^2$ has mean 1; again large values of $H^2$ indicate greater heterogeneity.

Two related statistics [20] are commonly quoted:

$$H^2 = \frac{Q}{K-1}$$

and

$$I^2 = \begin{cases} (H^2 - 1)/H^2 & \text{if } Q > (K-1) \\ 0 & \text{otherwise} \end{cases}$$

Under the null hypothesis that $\tau^2 = 0$, $Q$ has mean $K - 1$, so $H^2$ has mean 1; again large values of $H^2$ indicate greater heterogeneity. $I^2$ is a scaled version of $H^2$, lying between 0 and 1 (or 0 % and 100 %). Again, large values are consistent with heterogeneity, although for given $\tau^2$, values of $I^2$ will increase as the sample sizes of the component trials increase [32].

**Fig. 2.6** Forest plot for the bronchoconstriction meta-analysis [37] showing a prediction interval which was generated using argument prediction=TRUE in the forest.meta command.

$$Q \sim \chi^2_{K-1},$$
Example 2.10 For the bronchoconstriction meta-analysis, estimates of the measures of heterogeneity (\( \tau^2 = 2.44, H = 1.05 \) [1; 1.35], \( I^2 = 8.9\% \) [0\%; 45.3\%]) and the test for heterogeneity (\( Q = 17.57, p\text{-value} = 0.35 \)) are given in Fig. 2.2. All these quantities indicate that not much statistical heterogeneity is present. Accordingly, as both fixed effect and random effects are similar and show very strong evidence of an effect, and there is no evidence of heterogeneity, we conclude there is strong evidence Nedocromil sodium ameliorates post-exercise bronchoconstriction.

Example 2.11 For the depression meta-analysis, estimates of the measures of heterogeneity (\( \tau^2 = 0.23, H = 1.91 \) [1.5; 2.43], \( I^2 = 72.5\% \) [55.4\%; 83.1\%]) and the test for heterogeneity (\( Q = 58.27, p\text{-value} < 0.0001 \)) can be found in Fig. 2.4. All these quantities indicate that very large statistical heterogeneity is present. Despite this very large statistical heterogeneity both fixed effect and random effects meta-analysis show a statistically significant beneficial effect of tricyclic antidepressants. Furthermore, only 1 of 17 trials shows a detrimental effect of tricyclic antidepressants. Accordingly, we conclude there is strong evidence for a beneficial effect of tricyclic antidepressants; however, the size of the effect is unclear.

2.5 Subgroup Analysis

From time to time we need to work with subgroups of studies in a meta-analysis. The various R commands for meta-analysis in the R package \texttt{meta} support a \texttt{byvar} option, i.e. conduct a subgroup analysis by a variable, which makes this straightforward. We now illustrate its use. More technical details on subgroup analyses are provided in Sect. 4.3.

Example 2.12 Poole and Black [31] report a meta-analysis of mucolytic agents versus placebo for patients with chronic bronchitis and/or chronic obstructive pulmonary disease. The outcome is the mean number of acute exacerbations per month. Acute exacerbation is defined as an increase in cough and in the volume and/or purulence of sputum. As all studies report a mean number of exacerbations, we can work with mean differences, rather than standardised mean differences. R code to read in the data is given in Fig. 2.7. Notice that studies 5 and 12 (Jackson 1984, Grillage 1985) have zero standard errors.

We do a meta-analysis of the chronic bronchitis data using the following R command:

```r
> mc3 <- metacont(Ne, Me, Se, Nc, Mc, Sc, data=data3, + studlab=paste(author, year))
Warning message:
In metacont(Ne, Me, Se, Nc, Mc, Sc, data = data3, :
Studies with non-positive values for sd.e or sd.c get no weight in meta-analysis.
```
# 1. Read in the data:
> data3 <- read.csv("dataset03.csv")

# 2. As usual, to view an object, type its name:
> data3

Fig. 2.7 Reading in data from meta-analysis of mucolytic agents versus placebo for patients with chronic bronchitis and/or chronic obstructive pulmonary disease [31]

A warning has been printed for studies with zero weights. We can verify that these are the Jackson 1984 and Grillage 1985 trials:

> mc3$studlab[mc3$w.fixed==0]
[1] "Jackson 1984" "Grillage 1985"

The result of the meta-analysis is given by

> print(summary(mc3), digits=2)
Number of studies combined: k=21

<table>
<thead>
<tr>
<th>MD</th>
<th>95%-CI</th>
<th>z</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fixed effect model</td>
<td>-0.05 [-0.05; -0.04]</td>
<td>-10.06</td>
<td>&lt; 0.0001</td>
</tr>
<tr>
<td>Random effects model</td>
<td>-0.08 [-0.11; -0.05]</td>
<td>-5.82</td>
<td>&lt; 0.0001</td>
</tr>
</tbody>
</table>

Quantifying heterogeneity:

\[
tau^2 = 0.0027; H = 2.63 [2.19; 3.15]; I^2 = 85.5\% [79.1\%; 89.9\%]
\]

Test of heterogeneity:

\[
Q \text{ d.f. p-value} = 138.08 \text{ 20 < 0.0001}
\]

Details on meta-analytical method:
- Inverse variance method
- DerSimonian-Laird estimator for \(\tau^2\)
The results indicate significant between-study heterogeneity \((Q = 138, p < 0.0001)\) with \(I^2 = 85.5\%\). Looking at the data (Fig. 2.7), subgroup information is available for study duration: studies whose duration was greater or less than three months.

A subgroup analysis can be done by using argument `byvar` in the original call of the `metacont` function:

```r
> mc3s <- metacont(Ne, Me, Se, Nc, Mc, Sc, data=data3, 
+     studlab=paste(author, year), 
+     byvar=duration, print.byvar=FALSE)
```

Another more convenient way is to update the original meta-analysis by using the `update.meta` function from R package `meta`:\(^8\)

```r
> mc3s <- update(mc3, byvar=duration, print.byvar=FALSE)
```

The `update.meta` function is a wrapper function for the `metacont` function as well as other R functions discussed in the following chapters. Using the `update.meta` function we only have to specify arguments that should be changed as all other arguments are kept fixed. Note, in order for the `update.meta` function to work the data used in the original function call has to be part of R object `mc3`. This is—by default—the case as argument `keepdata` is equal to `TRUE`. Applying the `update.meta` function to an R object that was created with argument `keepdata=FALSE` would result in a descriptive warning message.

Results of a meta-analysis with subgroups are given by the following R command.

```r
> print(summary(mc3s), digits=2)
```

<table>
<thead>
<tr>
<th></th>
<th>MD</th>
<th>95%-CI</th>
<th>z</th>
<th>p-value</th>
</tr>

<td>-0.08</td>
<td>[-0.11; -0.05]</td>
<td>-5.82</td>
<td>&lt; 0.0001</td>
</tr>
</tbody>
</table>

Quantifying heterogeneity:

\(\tau^2 = 0.0027; H = 2.63 [2.19; 3.15]; I^2 = 85.5% [79.1%; 89.9%]\)

Test of heterogeneity:

\(Q\) d.f.  \(p\)-value

\(138.08\)  20   < 0.0001

Results for subgroups (fixed effect model):

<table>
<thead>
<tr>
<th></th>
<th>MD</th>
<th>95%-CI</th>
<th>(Q)</th>
<th>(\tau^2)</th>
<th>(I^2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;= 3 months</td>
<td>4  -0.13</td>
<td>[-0.17; -0.09]</td>
<td>22.43</td>
<td>0.035</td>
<td>86.6%</td>
</tr>
<tr>
<td>&gt; 3 months</td>
<td>17 -0.04</td>
<td>[-0.05; -0.03]</td>
<td>94.92</td>
<td>0.002</td>
<td>83.1%</td>
</tr>
</tbody>
</table>

Test for subgroup differences (fixed effect model):

\(Q\) d.f.  \(p\)-value

---

\(^8\)R function `update` is a generic function like `print` or `summary`. 
Between groups 20.73 1 < 0.0001
Within groups 117.35 19 < 0.0001

Results for subgroups (random effects model):
\[ k \quad MD \quad 95\%-CI \quad Q \quad \tau^2 \quad I^2 \]
\[
\leq 3 \text{ months} \quad 4 \quad -0.28 \quad [-0.50; -0.05] \quad 22.43 \quad 0.035 \quad 86.6\% \\
> 3 \text{ months} \quad 17 \quad -0.06 \quad [-0.09; -0.04] \quad 94.92 \quad 0.002 \quad 83.1\% 
\]

Test for subgroup differences (random effects model):
\[ Q \quad d.f. \quad p-value \]
Between groups 3.41 1 0.0647

Details on meta-analytical method:
- Inverse variance method
- DerSimonian-Laird estimator for \( \tau^2 \)

The results for the fixed effect model show that between-group heterogeneity is highly statistically significant (\( Q = 20.73 \) on 1 degrees of freedom) as well as within-group heterogeneity (\( Q = 117.35 \), 19 degrees of freedom). Further, the fixed effect estimates (\(-0.13\), short duration; \(-0.04\), long duration) are not that different. While short duration studies seem to have far fewer patients, the effect appears similar; study duration does not appear to be the source of the high degree of heterogeneity in these data. This observation is supported by the results for the random effects model (between-study heterogeneity: \( Q =3.41 \), 1 degrees of freedom).

A forest plot with subgroups for length of duration, which is shown in Fig. 2.8, can be produced using the following R command.

```r
> forest(mc3s, xlim=c(-0.5, 0.2),
+       xlab="Difference in mean number of acute exacerbations per month")
```

The argument `subset` which has been used before to select a single study can also be used to conduct a meta-analysis of a subgroup of studies, e.g. for studies with short study duration:

```r
> print(metacont(Ne, Me, Se, Nc, Mc, Sc, data=data3,
+       subset=duration="<= 3 months",
+       studlab=paste(author, year)),
+       digits=2)

*** Output truncated ***
Number of studies combined: \( k = 4 \)

\[
\begin{array}{lllll}
\text{MD} & \text{95\%-CI} & z & \text{p-value} \\

Or alternatively using the `update.meta` function:

```r
> print(update(mc3, subset=duration="<= 3 months"),
+       digits=2)
```
2.6 Meta-Analysis of Other Outcomes

In this section, the application of the generic inverse variance method to other outcomes will be described. All examples use the `metagen` function to conduct the meta-analysis. Other functions are available in R package `meta` for specific...
outcomes:

- `metacor` function for meta-analysis of correlations,
- `metainc` function for meta-analysis of incidence rate ratios,
- `metaprop` function for meta-analysis of single proportions.

The first two R functions are not covered in this book and the `metaprop` function is only briefly used in Chap. 9 to calculate confidence intervals for sensitivities and specificities. The corresponding help pages of these functions give further details on these methods as well as a couple of examples.

### 2.6.1 Meta-Analysis with Survival Outcomes

Statistical methods for binary data are described in detail in Chap. 3. Very often not only the information that an event occurred but also when the event happened is of central interest. This type of data is called time-to-event or survival data if the event of interest is death. Time to an event is a continuous quantity, however, in contrast to the examples with continuous outcomes used so far time to an event can typically not be observed for all participants as the maximum follow-up time is limited in a study. Patients where the event of interest did not occur during the follow-up period are called *censored* observations. Censoring is a distinguishing feature of time-to-event data. Another important aspect of time-to-event data, not covered in this book, are competing events, e.g. time to either cardiovascular or non-cardiovascular death. In this situation only the time to death either due to a cardiovascular or non-cardiovascular reason can be observed. Specific statistical methods for survival data have been developed [2, 24] and should be used in the analysis.

In survival analysis the hazard function, i.e. a function describing the instantaneous risk of dying given survival up to a specific timepoint, plays a central role. To compare two treatments the hazard ratio, i.e. a ratio of hazard functions, is typically used. The interpretation of a hazard ratio is similar to a risk ratio which is introduced in Sect. 3.1.2.

A meta-analysis with survival time outcomes is typically based on the hazard ratio as measure of treatment effect [26]. Accordingly, the logarithm of the hazard ratio and its standard error are the basic quantities utilised in meta-analysis. As hazard ratio and corresponding standard error are not always reported in publications, several methods exist to derive these quantities, e.g. from published survival curves [26, 42].

The generic inverse variance method can be used straightforward with log hazard ratio $\hat{\theta}_k$ and its standard error $\text{S.E.}(\hat{\theta}_k)$, for study $k$, $k = 1, \ldots, K$.

Using these quantities, all methods described in Sects. 2.2 and 2.3 can be used for meta-analysis. In the following example we consider the most basic case, i.e. fixed effect and random effects meta-analysis using the DerSimonian–Laird method to estimate the between-study variance $\tau^2$. 
2.6 Meta-Analysis of Other Outcomes

Example 2.13 Steurer et al. [38] conducted a Cochrane review to evaluate the effect of single-agent purine analogues for the treatment of chronic lymphocytic leukaemia. Data for the main outcome overall survival are reported in Fig. 2.9. Columns logHR and selogHR correspond to the log hazard ratio and its standard error.

The following R command can be used to conduct a meta-analysis using the generic inverse variance method.

```r
> mg1 <- metagen(logHR, selogHR, 
+ studlab=paste(author, year), data=data4, 
+ sm="HR")
```

Specifying argument `sm="HR"`, it is assumed that hazard ratios are entered on the log scale. If hazard ratios instead of log hazard ratios are available in a dataset, the base `log` function can be used to transform the hazard ratio, e.g. `metagen(log(HR), ...)`. Regardless of the input of hazard ratios or log hazard ratios, the `metagen` function expects that the standard error from the log hazard ratio and not the standard error of the hazard ratio is provided as input for argument `seTE`. Note, sample sizes given in columns `Ne` and `Nc` in Fig. 2.9 are not utilised in the calculations.

As usual we can print the results of the meta-analysis.

```r
> print(mg1, digits=2)

\begin{verbatim}
<table>
<thead>
<tr>
<th></th>
<th>HR</th>
<th>95%-CI</th>
<th>%W(fixed)</th>
<th>%W(random)</th>
</tr>
</thead>
<tbody>
<tr>

</tbody>
</table>
\end{verbatim}

Quantifying heterogeneity:
\[ \hat{\tau}^2 = 0.0061; H = 1.1 \ [1; 2.81]; I^2 = 17.2\% \ [0%; 87.3\%] \]
Test of heterogeneity:

<table>
<thead>
<tr>
<th>Q</th>
<th>d.f.</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>3.62</td>
<td>3</td>
<td>0.3049</td>
</tr>
</tbody>
</table>

Details on meta-analytical method:
- Inverse variance method
- DerSimonian-Laird estimator for \( \tau^2 \)

These results correspond to those reported in [38].

### 2.6.2 Meta-Analysis of Cross-Over Trials

Until now methods have been described to conduct a meta-analysis of trials comparing two parallel treatment groups. Cross-over trials are another popular design to compare treatments [23]. In a cross-over trial each participant serves as his/her own control. Accordingly, between-patient variation is removed from the treatment comparison resulting in a smaller number of patients to achieve the same statistical power. A typical setting for a cross-over trial is chronic but stable diseases, i.e. a patient neither gets cured nor does the condition (dramatically) worsen over time.

In a simple cross-over design, a patient is randomly assigned to treatment sequence AB or BA, i.e. either receiving treatment A first and “cross-over” to treatment B or vice versa. Typically, the first and second treatment period are separated by a so-called washout period such that the effect of the treatment effect in the first treatment period is not carried over to the second treatment period. In principle, longer sequences of two treatments A and B are possible, e.g. ABBA. Note, the first period of a cross-over trial is equivalent to a parallel group study design.

Statistical methods for meta-analysis of cross-over trials and the combination of parallel group and cross-over trials have been described in a series of papers in Statistics in Medicine [5, 6, 8]. For the meta-analysis of cross-over trials with a continuous outcome the generic inverse variance method can be used [5].

**Example 2.14** Curtin et al. [5, Table 2] report the results of 12 parallel group and 21 cross-over trials to evaluate the effect of potassium supplementation on the reduction of systolic and diastolic blood pressure. Here, we only look at the 21 cross-over trials and diastolic blood pressure as outcome of interest.

Mean difference in diastolic blood pressure (column `mean`) and its standard error (SE) as well as the within-patient correlation (corr) are given in Fig. 2.10. Correlations are not utilised in the meta-analysis, however, the values give some indication on the gain in precision by using a cross-over design. All correlations are above zero and ranging from 0.29 to 0.88. Accordingly, using a cross-over design results in a gain in precision in all trials.

</tbody>
</table>

Fig. 2.10 Data from meta-analysis of potassium supplementation for blood pressure reduction [5]

The following R code can be used for the meta-analysis of these cross-over trials

```r
> mg2 <- metagen(mean, SE, studlab=paste(author, year),
+                 data=data5, sm="MD")
```

which yields the results

```r
> print(summary(mg2), digits=2)
```

Number of studies combined: k=21

<table>
<thead>
<tr>
<th></th>
<th>MD</th>
<th>95%-CI</th>
<th>z</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fixed effect model</td>
<td>-3.71</td>
<td>[-4.32; -3.11]</td>
<td>-12.03</td>
<td>&lt; 0.0001</td>
</tr>
<tr>
<td>Random effects model</td>
<td>-2.38</td>
<td>[-4.76; -0.01]</td>
<td>-1.96</td>
<td>0.0495</td>
</tr>
</tbody>
</table>

Quantifying heterogeneity:

- $\tau^2 = 27.03$; $H = 3.66$ [3.14; 4.25]; $I^2 = 92.5%$ [89.9%; 94.5%]

Test of heterogeneity:

- $Q$ d.f. p-value
- $267.24$ 20 < 0.0001
Details on meta-analytical method:
- Inverse variance method
- DerSimonian-Laird estimator for $\tau^2$

Both fixed effect and random effects model show a statistically significant reduction in diastolic blood pressure for potassium supplementation. Due to the very large between-study heterogeneity the confidence interval for the random effects estimate is much wider than the confidence interval for the fixed effect estimate. Accordingly, the $p$-value for the random effects model is much larger.

Results for the fixed effect model have also been reported in [5, Table 3] and are almost identical.

\[ \square \]

### 2.6.3 Meta-Analysis of Adjusted Treatment Effects

Another application of the generic inverse variance method is a meta-analysis of adjusted treatment effects, e.g. adjusted log odds ratios from a logistic regression model [1] or log hazard ratios from a Cox regression model [24].

**Example 2.15** Greenland and Longnecker [12] describe a method to combine trend estimates from summarised dose–response data. A meta-analysis of 16 case–control studies evaluating the impact of alcohol consumption on breast cancer risk was used as an illustrative example (see [12, Table 3]).

Data for these studies are given in Fig. 2.11. For meta-analysis the adjusted log risk ratio (column $b$) and its standard error (SE) are utilised. In order to report results as log risk ratios like the authors [12] we use argument `backtransf=FALSE`.

```r
> # 1. Read in the data
> data6 <- read.csv("dataset06.csv")
> # 2. Print data
> data6

<table>

</tbody>
</table>
```

**Fig. 2.11** Data from meta-analysis evaluating impact of alcohol consumption on breast cancer risk [12]
The results for the meta-analysis are as follows.

Number of studies combined: k=16

<table>
<thead>
<tr>
<th>Method</th>
<th>logRR</th>
<th>95%-CI</th>
<th>z</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fixed effect model</td>
<td>0.0082</td>
<td>[0.0056; 0.0108]</td>
<td>6.2409</td>
<td>&lt; 0.0001</td>
</tr>
<tr>
<td>Random effects model</td>
<td>0.0131</td>
<td>[0.0062; 0.0199]</td>
<td>3.7298</td>
<td>0.0002</td>
</tr>
</tbody>
</table>

Quantifying heterogeneity:

\[ \tau^2 = 0.0001; \quad H = 2.24 \quad [1.78; 2.82]; \quad I^2 = 80.1\% \quad [68.5\%; 87.4\%] \]

Test of heterogeneity:

\[ Q \quad \text{d.f.} \quad \text{p-value} \]

75.31 15 < 0.0001

Details on meta-analytical method:

- Inverse variance method
- DerSimonian-Laird estimator for \( \tau^2 \)

As we used argument `backtransf=FALSE`, treatment estimates are reported on the log scale (see \( \text{logRR} \) in the printout). Results for the fixed effect model are identical to those reported in [12].

2.7 Summary

In this chapter the generic inverse variance method and its application in meta-analysis has been described in detail using continuous outcomes. Both fixed effect and random effects methods have been introduced. We have shown how typical data can be used with the `metacont` and `metagen` function, respectively, and how the results of a meta-analysis can be printed and plotted.

We also discussed various methods for estimating the between-study variance \( r^2 \) and the Hartung–Knapp adjustment has been described as an alternative method to the classic random effects method. Furthermore, we have illustrated the use of the `byvar` option, which makes subgroup analysis straightforward. More details on tests for subgroup differences are provided in Sect. 4.3.

Lastly, the generic inverse variance method has been used in very different settings (survival outcomes, cross-over trials, adjusted treatment effects) indicating the wide applicability of the method.

In the next chapter, we describe the analogue of these analyses for binary data.
