2 Units of Radiation Protection

“All composed things tend to decay.”

Buddha 563–483 B. C.

A large number of units has been proposed and used in the course of historical development and research in the field of radioactivity. Only those which have survived to today shall be used and defined here. I will introduce the modern units which are recommended by the International Commission on Radiological Protection (ICRP). In addition, I will also mention those units which are still in use in countries like in the USA, and give the relations to the ICRP-recommended units used in Europe and elsewhere.

The unit of activity is becquerel (Bq). 1 Bq is one decay per second. The old unit curie (Ci) corresponds to the activity of 1 g of radium-226:

\[
1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq},
\]

\[
1 \text{ Bq} = 27 \times 10^{-12} \text{ Ci} = 27 \text{ pCi}.
\]

In radioactive decays the number of decaying nuclei \(\Delta N\) is proportional to the number of existing nuclei \(N\) and the observation time \(\Delta t\). The number of nuclei decreases by decay. This fact gives the negative sign for \(\Delta N\). Therefore, one has

\[
\Delta N \sim -N \Delta t.
\]

Since the decay rate changes in time it makes sense to use very small, indeed infinitesimal times \(dt\) and numbers \(dN\) (see Appendix Q),

\[
dN \sim -N \, dt.
\]

Starting from this relation one obtains the equation by introducing a constant of proportionality, namely, the decay constant \(\lambda\),

\[
\frac{\text{1 becquerel (Bq)}}{\text{1 decay per second}} = \frac{\text{1 curie (Ci)}}{3.7 \times 10^{10} \text{ Bq}} = \frac{\text{1 Bq}}{27 \times 10^{-12} \text{ Ci}} = 27 \text{ pCi}.
\]

\[
\frac{\text{1 Ci}}{3.7 \times 10^{10} \text{ Bq}},
\]

\[
\frac{1 \text{ Bq}}{27 \times 10^{-12} \text{ Ci}} = 27 \text{ pCi}.
\]

(2.1)

\[
\Delta N \sim -N \Delta t.
\]

(2.2)

Since the decay rate changes in time it makes sense to use very small, indeed infinitesimal times \(dt\) and numbers \(dN\) (see Appendix Q),

\[
dN \sim -N \, dt.
\]

(2.3)

Starting from this relation one obtains the equation by introducing a constant of proportionality, namely, the decay constant \(\lambda\),

\[
\lambda = \frac{\text{decay constant}}{27 \times 10^{-12} \text{ Ci}} = \frac{1 \text{ Ci}}{3.7 \times 10^{10} \text{ Bq}} = \frac{1 \text{ Bq}}{27 \text{ pCi}}.
\]

(2.4)

\[
\frac{\text{cgs}}{\text{SI}} = \frac{1 \text{ curie (Ci)}}{3.7 \times 10^{10} \text{ Bq}},
\]

\[
\frac{1 \text{ Bq}}{27 \times 10^{-12} \text{ Ci}} = 27 \text{ pCi}.
\]

(2.5)
2. Units of Radiation Protection

\[ \frac{dN}{dt} = -\lambda N \quad (2.4) \]

Such a differential equation can be solved generally by the so-called exponential function (see Appendix Q):

\[ N = N_0 e^{-\lambda t} \quad (2.5) \]

\( N_0 \) characterizes the number of nuclei existing at time \( t = 0 \), i.e. the number of originally existing atomic nuclei. The number \( e = 2.71828 \ldots \) is the basis of the natural logarithm (see Appendix Q). Since the exponent of the exponential function has to be without dimension, the physical unit of the decay constant is second\(^{-1}\). The decay constant \( \lambda \) is related to the lifetime of the radioactive source as

\[ \lambda = \frac{1}{\tau} \quad (2.6) \]

One has to distinguish the half-life \( T_{1/2} \) from the lifetime. The half-life is the time after which a half of the initially existing atomic nuclei has decayed. After another half-life a half of the remaining nuclei will have decayed, so that one is left with only one quarter of the original nuclei. That means, say, after 10 half-lives, there is still a fraction of \( 2^{-10} \) nuclei which has not decayed. Because of

\[ N(t = T_{1/2}) = \frac{N_0}{2} = N_0 e^{-T_{1/2}/\tau} \quad (2.7) \]

we will get, applying the rules of exponential functions and natural logarithms as explained in Appendix Q,\(^2\)

\[ \frac{1}{2} = e^{-T_{1/2}/\tau} , \]
\[ e^{T_{1/2}/\tau} = 2 , \]
\[ T_{1/2}/\tau = \ln 2 \]
or \[ T_{1/2} = \tau \ln 2 \quad (2.8) \]

The decay constant \( \lambda \) of an unstable radioactive nucleus is obtained as

\[ \lambda = \frac{1}{\tau} = \frac{\ln 2}{T_{1/2}} \quad (2.9) \]

The activity \( A \) of a radioactive source characterizes the number of decays per second. Therefore, the activity \( A \) is equal to the change

\(^2\) The exponential function \( e^x \) and the natural logarithm \( \ln x \) are operations which are available on most, even simple, non-scientific pocket calculators.
rate $\Delta N$ of existing atomic nuclei in the time $\Delta t$. Because a decreasing number of atomic nuclei represents a positive activity, one defines

$$A = -\frac{\Delta N}{\Delta t}.$$  \hspace{1cm} (2.10)

For infinitesimal time intervals $dt$ one has

$$A = -\frac{dN}{dt}.$$  \hspace{1cm} (2.11)

With the help of Eq. (2.5) and the rules of calculus as presented in Appendix Q one obtains:

$$A = -\frac{d}{dt} (N_0 e^{-\lambda t}) = \lambda N_0 e^{-\lambda t} = \lambda N = \frac{1}{\tau} N.$$  \hspace{1cm} (2.12)

Radioactive sources with a large lifetime $\tau$ (or, equivalently, half-life $T_{1/2}$) naturally have lower activities if a given number of nuclei is considered.

The activity in Bq does not say very much about possible biological effects. These are related to the deposited energy by the radioactive source in matter. The energy dose $D$ (absorbed energy

"I rather stick to the old activity unit. 'Micro-curie' sounds so much better than 'mega-becquerel'!"

© by Claus Grupen
\(\Delta W\) per mass unit \(\Delta m\),

\[
D = \frac{\Delta W}{\Delta m} = \frac{1}{\rho} \frac{\Delta W}{\Delta V}
\]  

(\(\rho\) – density, \(\Delta V\) – volume element\(^3\)), is measured in gray:

\[
1 \text{ gray (Gy)} = 1 \text{ joule (J) / 1 kilogram (kg)}.
\]  

Gray is related to the old unit rad (radiation absorbed dose, 1 rad = 100 erg/g; still in use in the US) according to:\(^4\)

\[
1 \text{ Gy} = 100 \text{ rad}.
\]  

For indirectly ionizing radiation (i.e. photons and neutrons, but not electrons and other charged particles) a further quantity characterizing the energy dose, the ‘kerma’, is defined. Kerma is an abbreviation for “kinetic energy released per unit mass”.\(^5\) The kerma \(k\) is defined as the sum of the initial energies of all charged particles, \(\Delta E\), liberated in a volume element \(\Delta V\) by indirectly ionizing radiation divided by the mass \(\Delta m\) of this volume element:

\[
k = \frac{\Delta E}{\Delta m} = \frac{1}{\rho} \frac{\Delta E}{\Delta V},
\]  

where \(\rho\) is the density of the absorbing material.

We see that kerma relates only to the energy transferred to the charged particles: it does not depend on which fraction of the energies of the charged particles is transported out of the volume by particle motion or by bremsstrahlung. Therefore, kerma is sometimes also called dose unit of the first interaction step. The unit of kerma is also gray (Gy).

Gray and rad describe the pure physical energy absorption. These units cannot easily be translated into the biological effect of radiation. Electrons, for example, ionize relatively weakly while, in contrast, \(\alpha\) rays are characterized by a high ionization density. Therefore, biological repair mechanisms cannot be very effective in the latter case. The relative biological effectiveness (RBE) depends on the type of radiation, the radiation energy, the temporal distribution of the dose, and other quantities. The relative biological effectiveness is a factor by which we have to multiply the energy dose \(D\)

\(^3\) A volume element, sometimes also called ‘unit volume’, is the differential element \(\Delta V\) whose volume integral over some range in a given coordinate system gives the total volume \(V\).

\(^4\) 1 joule (J) = 1 watt second (Ws) = \(1 \text{ kg m}^2\text{s}^{-2}\) = \(10^7 \text{ g cm}^2\text{s}^{-2}\) = \(10^7\) erg

\(^5\) Occasionally one also finds “kinetic energy released in matter (or: in material)”.

\(\text{dose unit of the first interaction step}\)

\(\text{relative biological effectiveness}\)
of our chosen type of radiation giving the energy dose \( D_\gamma \) of X rays or \( \gamma \) rays which would have the same biological effect,

\[
\text{RBE} = \frac{D_\gamma}{D} .
\] (2.17)

Since it is not always known in radiation protection which biological effects one has to refer to in a specific case, instead of the complicated energy-, radiation-, and dose-rate-dependent RBE factors one uses the so-called quality factor \( Q \) to assess the effect of a physical energy deposition. This leads to the dose equivalent \( H \),

\[
H = Q f D .
\] (2.18)

\( H \) is measured in sievert (Sv). The factor \( f \) considers further radiation-relevant factors such as the dose-rate dependence or reduced biological effects by a periodic irradiation. Such a technique of intermittent radiation is used in cancer therapy: if a patient should receive, say, a dose of 2 Sv to destroy a tumor, this dose is applied e.g. in ten separate fractions of 0.2 Sv, because in the intervals between these fractions the healthy tissue will recover more easily in contrast to the tumor tissue. A typical interval between subsequent fractions of irradiations is a day. All in all the product of the quality factor \( Q \) and the modifying factor \( f \) assesses the biological radiation effect of an absorbed dose \( D \). Therefore, this product \( q = Q f \) is called the weighting factor. Since both the quality factor \( Q \) and the correction factor \( f \) are dimensionless, so is the weighting factor \( q \), and the unit of the equivalent dose is also J/kg.\(^6\) The old unit rem (roentgen equivalent man), still in use in the United States, is related to sievert according to

\[
1 \text{ Sv} = 100 \text{ rem} .
\] (2.19)

Nowadays the weighting factors \( q \) are called radiation weighting factors following a recommendation by the International Commission on Radiological Protection. These radiation weighting factors \( w_R \) depend on the type of radiation and for neutrons also on their energy. The most recent definition of radiation weighting factors following the recommendation of the International Commission on Radiological Protection is given in Table 2.1.

For the radiation field \( R \) one gets the dose equivalent \( H_R \) from the energy dose \( D_R \) according to

\(^6\) The energy dose \( D \) is measured in Gy and the equivalent dose \( H \) in Sv, therefore, the weighting factor \( q \) in principle has the unit Sv/Gy. However, both Gy and Sv have the same physical unit J/kg, where Gy only considers the physical effect while Sv also takes the biological effect into account.

$H_R = w_R D_R$. (2.20)

Figure 2.1 shows photographic records taken with a diffusion cloud chamber in normal air. They clearly demonstrate the strong ionizing effect of $\alpha$ particles from the radon decay chain (left). At the same time the weakly ionizing effect of decay electrons is visible. Their tracks in the diffusion cloud chamber are characterized by multiple scattering and large bending angles (right image).

Apart from these units another quantity is used for the amount of created charge, the roentgen (R). One roentgen is that radiation dose of $X$ rays and $\gamma$ rays, which liberates one electrostatic charge unit

---

7 The energy-dependent radiation weighting factor for neutrons can be approximated by the function $w_R = 5 + 17 e^{-\frac{1}{6}(\ln(2 E_n))^2}$, where the neutron energy $E_n$ is measured in MeV.

8 Muons are short-lived elementary particles which are produced predominantly in cosmic radiation (see also Sect. 11.1).
2. Units of Radiation Protection

Figure 2.1
Tracks of α particles and electrons in a diffusion cloud chamber exposed to normal air in buildings. The different lengths and widths of α-particle tracks (left image) originate from projection effects of electrons and one of ions in 1 cm³ of air (at standard temperature and pressure).

**ion dose**
If the unit roentgen is expressed by the ion dose $I$ in coulomb/kg, one obtains

$$1 \text{ R} = 2.58 \times 10^{-4} \text{ C/kg} \ .$$

(2.21)

The tissue equivalent of roentgen is given by

$$1 \text{ R} = 0.88 \text{ rad} = 8.8 \text{ mGy} \ .$$

(2.22)

For an approximate estimate of body doses for photon radiation it is generally sufficient to work out the photon equivalent dose according to

$$H_X = \eta I_S \ ,$$

(2.23)

where $I_S$ is the standard ion dose in roentgen and the scale factor is given by

$$\eta = 38.8 \text{ Sv (C/kg)}^{-1} = 0.01 \text{ Sv/R} \ .$$

(2.24)

To consider the time dependence of the dose equivalent or ion dose, we use the dose rate. The energy-dose rate is the change of the energy dose $\Delta D$ in the time $\Delta t$. Since the dose rate changes rapidly, particularly for radioactive sources with short half-life, it is advisable to use the differential notation (see Appendix Q). Depending on whether one prefers the notation $\left( \frac{d}{dt} \right)$ introduced by Leibniz or the notation favored by Newton, as characterized by a dot over the quantity, one writes for the energy-dose rate

$$\frac{dD}{dt} \ \text{or, equivalently,} \ \dot{D} \ .$$

(2.25)

**dose-equivalent rate**
Correspondingly, also the dose-equivalent rate is given by

$$\frac{dH}{dt} \equiv \dot{H} \ .$$

(2.26)
and the ion-dose rate by

\[ \frac{dI}{dt} \equiv \dot{I}. \]  

(2.27)

The physical units of these quantities are:

\[ [\dot{D}] = \frac{J}{kg \ s} = \frac{Ws}{kg \ s} = \frac{W}{kg}, \]  

(2.28)

\[ [\dot{H}] = [\dot{D}], \]  

(2.29)

\[ [\dot{I}] = \frac{C}{kg \ s} = \frac{As}{kg \ s} = \frac{A}{kg}. \]  

(2.30)

\( \dot{D} \) and \( \dot{H} \) are therefore measured in watt per kilogram and \( \dot{I} \) in ampere per kg.

The received dose can be related to the whole body (whole-body dose) or also only to specific parts of the body (partial-body dose). The dose equivalent that has accumulated within 50 years after a single incorporation\(^9\) of radioactive substances in a certain organ or tissue is called ‘50-years dose-equivalent commitment’.

If a radiation exposure with an average per capita dose-equivalent rate \( \dot{H}(t) \) for a population group over an extended period has occurred, a dose-equivalent commitment is defined by

\[ H_f = \sum \dot{H}(t) \Delta t, \]  

(2.31)

where one has to sum over the relevant time intervals \( \Delta t \). If this dose rate \( \dot{H}(t) \) does not depend on the time, one has

\[ H_f = \dot{H} t, \]  

(2.32)

where \( t \) is the considered time interval.

The collective dose is the product of the total number of persons \( N \) by one person’s average dose \( \langle H \rangle \) in sievert or, more generally, the collective equivalent dose \( S \) is

\[ S = \sum_k P_k \langle H_k \rangle, \]  

(2.33)

\(^9\) When radioactive substances enter the human body, the radiation effects are different from those resulting from exposure to an external radiation source. Especially in the case of alpha radiation, which has a rather short range and normally never penetrates the skin, the exposure can be much more damaging after ingestion or inhalation. The terms ingestion and inhalation and the intake of radioactive compounds through wounds after accidents are usually subsumed under the expression incorporation.

</table>

where $\langle H_k \rangle$ is the per capita equivalent dose in an interval $H_k \ldots H_k + \Delta H_k$ and $P_k$ the number of persons with radiation exposures in this interval.

In many cases it is necessary to convert a partial-body dose into a whole-body dose. Therefore, a weighting factor $w_T$ has to be attributed to the irradiated organs of the body. This effective dose equivalent is defined as

$$H_{\text{eff}} = \sum_{T=1}^{n} w_T H_T,$$

(2.34)

where $H_T$ is the average dose equivalent in the irradiated organ or tissue and $w_T$ is the weighting factor for the $T$th organ or tissue.\(^{10}\)

For the purpose of radiation protection it is simply defined that the human has thirteen ‘organs’. The weighting factors are normalized to 1 ($\sum w_i = 1$). These tissue weighting factors are compiled in Table 2.2.

It is assumed that the inhomogeneous irradiation of the body with an effective dose equivalent $H_{\text{eff}}$ bears the same radiation risk as a homogeneous whole-body irradiation with $H = H_{\text{eff}}$.

The determination of the dose-equivalent rate by a pointlike radiation source of activity $A$ can be accomplished using the following formula:

$$\dot{H} = \Gamma \frac{A}{r^2}.$$  

(2.35)

In this equation $r$ is the distance from the radiation source (in meters) and $\Gamma$ a specific radiation constant which depends on the type and energy of the radiation. For $\beta$ rays additionally the traveling

---

\(^{10}\) In some cases the effective dose equivalent $H_{\text{eff}}$ is also denoted with $E$ in order to stress that in this case we are dealing with an effective dose.

</table>

The distance of electrons has to be considered. Table 2.3 lists the $\beta$ and $\gamma$ dose constants for some commonly used radiation sources. The $1/r^2$ dependence of the dose-equivalent rate is easily understood, if one considers that for isotropic emission (i.e. equally in all directions) the irradiated area for larger distances increases quadratically with distance $r$. The radiation emerging from the source has to pass through the surface of the virtual sphere (surface of sphere = $4\pi r^2$), consequently the radiation intensity per unit area decreases like $1/r^2$ ('solid-angle effect').

The differences in the $\beta$ and $\gamma$ dose constants originate from the fact that electrons will normally deposit all of their energy in the body while the absorption power of the body for $\gamma$ rays is much smaller. Differences in the $\beta$ or $\gamma$ dose constants for different radioisotopes have their origin in the different energy of the

---

\(^{11}\) A chemical element is characterized by the number of positively charged nucleons (i.e. protons, with proton number = $Z$). Furthermore there are neutrons in the atomic nucleus which are essential for the binding of nuclei (neutron number = $N$). The atomic mass $A$ is given by the sum of the proton and neutron numbers $Z + N$. Nuclei with fixed proton number but variable neutron number are called isotopes of the element with the atomic number $Z$. Isotopes which are radioactive are called radioisotopes. An isotope is characterized by the number of protons $Z$ and neutrons $N$ using the notation $^A_Z\text{Element}$. Since the name of the element is uniquely determined by $Z$, this index is frequently omitted, e.g. $^{132}\text{Cesium}$ or $^{137}\text{Cesium}$. 
emitted $\beta$ and $\gamma$ rays. As an example $^{137}$Cs radiates a photon of energy 662 keV and $^{60}$Co two $\gamma$ rays with energies 1.17 MeV and 1.33 MeV. Consequently the $\gamma$ dose constant for $^{60}$Co is larger than for $^{137}$Cs, even though the absorption coefficient for MeV photons is somewhat smaller compared to 662-keV photons.

A pointlike $^{137}$Cs $\gamma$-ray emitter of activity 10 MBq produces a dose-equivalent rate of 0.846 $\mu$Sv/h at a distance of 1 m. A $^{60}$Co source of the same activity leads to a dose-equivalent rate of 3.41 $\mu$Sv/h at the same distance. The dose-rate ratio of these two sources corresponds roughly to the ratio of the deposited energies.

### 2.1 Supplementary Information

**Example 1**

A radiation officer detects a contamination with $^{131}$I in a medical laboratory which leads to an ambient-dose rate of 1 mSv/h. He decides to seal the room and wait until the activity due to the iodine contamination has decayed to such a level that the ambient-dose rate is only 1 $\mu$Sv/h. For how long has the room to be sealed?

The half-life of the $^{131}$I isotope is 8 days. The dose rate and consequently the activity should be reduced by a factor of 1000. The decay law

$$N = N_0 e^{-t/\tau}$$

leads to a time dependence of the activity $A$ like
2.1 Supplementary Information

\[ A = A_0 e^{-t/\tau}, \]

where \( A_0 \) is the initial activity. With \( A/A_0 = 10^{-3} \) and \( \tau = T_{1/2}/\ln 2 \) one has

\[ \exp \left( -\frac{t \ln 2}{T_{1/2}} \right) = 10^{-3} \]

and

\[ t = \left( \frac{T_{1/2}}{\ln 2} \right) \ln 1000 = 79.7 \text{ days}. \]

Consequently about 10 half-lives ((1/2)\(10 = 1/1024\)) are required to reach the necessary reduction factor.

A historical example for the specific activity leads to the definition of the old unit curie:

The half-life of \(^{226}\text{Ra}\) is 1600 years. This leads to the specific activity (i.e. the activity per gram) of:

\[ A^* = \lambda N = \frac{\ln 2}{T_{1/2}} \frac{N_A}{M_{\text{Ra}}} = \frac{\ln 2}{1600 \text{ yr}} \frac{6.022 \times 10^{23}}{226} = 3.7 \times 10^{10} \text{ Bq} = 1 \text{ curie}. \]

\(N_A\) is the Avogadro constant and \(M_{\text{Ra}}\) the atomic weight of \(^{226}\text{Ra}\)-dium, 1 yr = 3.1536 \(\times 10^7\) s.)

The radiation units presented so far have been recommended by the International Commission on Radiological Protection (ICRP). In addition, also the International Commission on Radiation Units and Measurement (ICRU) has proposed a slightly modified concept of dose quantities in the field of radiation protection. These quantities differ from the units presented so far by higher specialization and stronger formalization. These specialized dosimetric units are frequently used in national radiation-protection regulations.

If in a specific tissue, organ, or part of the body, \(T\), the energy dose \(D_{T,R}\) is caused by a radiation field of type \(R\), then the equivalent or organ dose is obtained by using the radiation weighting factor \(w_R\) as follows:

\[ H_{T,R} = w_R D_{T,R}, \quad (2.36) \]

where \(w_R\) is the radiation weighting factor given in Table 2.1.

Equation (2.36) defines the partial-body doses \(T\) for a given radiation field \(R\). If several different types of radiation (\(\alpha\), \(\beta\), \(\gamma\), \(n\)) work together, the corresponding partial-body dose is given by

\[ H_T = \sum_R H_{T,R} = \sum_R w_R D_{T,R}. \quad (2.37) \]
The effective dose equivalent $H_{\text{eff}} = E$ can be derived from Eq. (2.37) by weighting the different energy doses with the tissue weighting factors $w_T$, which have been presented in Table 2.2:

$$E = H_{\text{eff}} = \sum_T w_T H_T = \sum_T w_T \sum_R w_R D_{T,R}.$$  \hspace{1cm} (2.38)

Furthermore, dose units for penetrating external radiation (depositing most of their energy in the first 10 mm of tissue) and for radiation of low penetration depth (70 μm skin depth) have been introduced in many national radiation-protection regulations. In personal dosimetry these operative units are denoted with $H_p(10)$, $H_p(0.07)$.

In the past these operative units had been determined with film badges (see Sect. 5.6). However, the measurement of the depth doses $H_p(10)$ and $H_p(0.07)$ with film badges is not very accurate. A precise value for the skin dose as derived from the penetration depth of the radiation can be obtained with more sophisticated dosimeters. Such a new type of dosimeter, called ‘sliding-shadow’ dosimeter, has been developed, which allows a reliable determination of the skin doses. These dosimeters are optimized for a depth-dose determination and allow at the same time a determination of energy and angle of incidence of photons, and they can further discriminate between $\beta$ and $\gamma$ rays.

The availability of this new measurement technique necessitated to convert the hitherto existing quantities $H_p(10)$ and $H_p(0.07)$ into the new quantities $H^*(10)$ and $H^*(0.07)$. The conversion factors depend on the photon energy and the angle of incidence. For environmental radiation, $\gamma$ rays or X rays from X-ray tubes with accelerating voltages below 50 kV and above 400 kV the conversion factor is 1; i.e. the old and new depth doses are identical. For $\gamma$ rays from radioactive sources which are frequently used as X-ray sources (e.g. $^{57}$Co, $^{67}$Ga, $^{75}$Se, $^{99m}$Tc, $^{153}$Gd, $^{153}$Sm, $^{169}$Yb, $^{170}$Tm, $^{186}$Re, $^{192}$Ir, $^{197}$Hg, $^{199}$Au, $^{201}$Tl, $^{241}$Am) and for the radiation field of X-ray tubes operated with accelerating voltages between 50 kV and 400 kV, the conversion factors are $H^*(10)/H_p(10) = 1.3$ and $H^*(0.07)/H_p(0.07) = 1.3$. This means that the depth doses as determined with the old film badges have to be increased by 30%.

More details on the new skin doses can be found in the article “New quantities in radiation protection and conversion coefficients”.

---

12 These ‘sliding-shadow’ dosimeters use a special arrangement of structured metal and plastic filters and directional indicators. In addition, $\beta$ rays can be distinguished from $\gamma$ rays, which is essential for a reliable individual depth-dose information. The different absorption coefficients of the filters used allow an accurate measurement of the skin dose over a wide energy range. The basic detector behind the arrangement of filters is still a sensitive film, like in the old film badge.
Proposal for a new unit for radiation protection

The common units for radiation doses (Gy, Sv) are not very persuasive for a broader audience. The layman also has difficulties to interpret a dose given in Gy or Sv. Even relatively low radiation exposures which can only be detected because of extraordinarily sensitive measurement devices (one can measure the decay of individual atomic nuclei without difficulty) occasionally lead to over-reactions in public discussions. It is, however, very important to express radiation levels, caused, for example, by CASTOR transports or nuclear power plants, in units which can be understood and interpreted by the layman. It is perfectly sufficient to appreciate the order of magnitude of a radiation exposure, i.e., in easily comprehensible and self-explaining units which can be judged upon intuitively.

Mankind has developed with permanent natural radiation caused by cosmic rays and terrestrial rays and by permanent incorporation by ingestion and inhalation of natural radioisotopes. There are no hints whatsoever that this radiation has created any biological defect, it may even have increased the biodiversity. The natural radiation dose is subject to regional variations, but the natural annual radiation dose does not fall below 2 mSv for anybody. This natural annual dose sets the scale on which to judge on additional radiation burdens by civilization, for example, by medical diagnosis.

It is therefore proposed to use this typical value of the inevitable annual dose (IAD) due to natural radiation as a scale against which additional radiation exposures should be judged in discussions in the public:

$$1\text{IAD} = 2\text{mSv}. $$

In these units the following table gives some typical radiation exposures.

<table>
<thead>
<tr>
<th>type of radiation exposure</th>
<th>dose in IAD</th>
</tr>
</thead>
<tbody>
<tr>
<td>X-ray of a tooth</td>
<td>0.005</td>
</tr>
<tr>
<td>radiation level by nuclear power plants</td>
<td>≤ 0.01/yr</td>
</tr>
<tr>
<td>CASTOR transport for accompanying persons</td>
<td>≤ 0.015</td>
</tr>
<tr>
<td>air flight London – New York</td>
<td>0.015</td>
</tr>
<tr>
<td>X-ray of the chest</td>
<td>0.05</td>
</tr>
<tr>
<td>mammography</td>
<td>0.25</td>
</tr>
<tr>
<td>scintigraphy of the thyroid gland</td>
<td>0.40</td>
</tr>
<tr>
<td>heavy smoker (more than 20 cigarettes per day)</td>
<td>0.50/yr</td>
</tr>
<tr>
<td>positron-emission tomography</td>
<td>4.0</td>
</tr>
<tr>
<td>computer tomography of the chest</td>
<td>5.0</td>
</tr>
<tr>
<td>limit for radiation-exposed persons in Europe</td>
<td>10</td>
</tr>
<tr>
<td>limit for radiation-exposed persons in the USA</td>
<td>25</td>
</tr>
<tr>
<td>maximum life dose for radiation-exposed persons in Europe</td>
<td>200</td>
</tr>
<tr>
<td>lethal dose</td>
<td>2000</td>
</tr>
<tr>
<td>local cancer therapy</td>
<td>≈ 30 000</td>
</tr>
</tbody>
</table>

Based on these numbers everybody can judge independently on the realistic risk caused by radiation exposures.

---

13 G. Charpak and R. L. Garwin proposed a similar unit; they set the scale by the body-intrinsic radioactivity which leads to an annual radiation dose of 0.2 mSv. They named this dose 1 DARI, where the acronym DARI stands for Dose Annuelle due aux Radiations Internes. Europhysics News 33/1, p. 14 (2002).
Summary

The essential units of radiation protection are becquerel (Bq) for the activity, gray (Gy) for the purely physical energy deposition per mass unit, and sievert (Sv) for the energy dose weighted by the biological effectiveness. A further characteristic quantity for a radioactive isotope is its half-life \( T_{1/2} \). Radioisotopes with large half-lives are associated with a low activity, and those with short half-lives with a high one. The activity alone is not a good measure for a possible biological damage. This damage depends on the type of emitter and, of course, on the distance to the radiation source.

2.2 Problems

**Problem 1**
A radioactive material possesses an approximately constant gamma activity of 1 GBq. Per decay 1.5 MeV are liberated. What is the daily energy dose if the ionizing radiation is absorbed in an amount of material of mass \( m = 10 \text{ kg} \)?

**Problem 2**
In a nuclear physics laboratory a researcher has inhaled dust of a \(^{90}\text{Sr}\) isotope by accident, which has lead to a dose rate of 1 \( \mu\text{Sv/h} \) in his body. The physical half-life of \(^{90}\text{Sr}\) is 28.5 yrs, the biological half-life for retention in the lung (see Chap. 13, Page 217) is only 80 days. How long does it take until the dose rate has decreased to 0.1 \( \mu\text{Sv/h} \)?

(The biological half-life is defined by the time until 50% of the activity is eliminated by the body by normal biological activity.)

**Problem 3**
At a distance of 2 m from a pointlike \(^{60}\text{Co}\) source a dose rate of 100 \( \mu\text{Sv/h} \) is measured. What is the activity of the source?

(To solve this problem you should use information from Figs. 3.4 and 4.4.)

**Problem 4**
The radioisotope technetium 99m is frequently used in nuclear medicine. \(^{99m}\text{Tc}\) is a metastable state of \(^{99}\text{Tc}\), it has a half-life of 6 h. What kind of activity has a patient who was administered an activity of 10 MBq \(^{99m}\text{Tc}\) for a kidney examination after a period of two days? For this estimate one can assume that the effective half-life can be approximated by the physical half-life.
