Chapter 2
The Basic Functions

2.1 Overview

The code you learn to write for your Arduino is very similar to the code you write in any other computer language. This implies that all the basic concepts remain the same and it is simply a matter of learning a new dialect. In the case of Arduino, the language is based on the C/C++ and can even be extended through C++ libraries. The IDE enables you to write a computer program, which is a set of step-by-step instructions that you then upload to the Arduino. Your Arduino will then carry out those instructions and interact with whatever you have connected to it. The Arduino includes many basic embedded functions, such as the functions for reading and writing to digital and analog input and output pins, interrupt functions, mathematical functions, and serial communication functions. Arduino functions are a convenient way to write code such as those for device drivers or commonly used utility functions. Furthermore, Arduino also consists of many built-in-examples. You just need to click on the toolbar menu: File → Examples to access them. These simple programs demonstrate all basic the Arduino commands. They span from a Sketch Bare Minimum, Digital, and Analog IO, to the use of Sensors and Displays.

For more information on the Arduino language, see the Language Reference section of the Arduino web site, http://arduino.cc/en/Reference/HomePage. All Arduino instructions are online.

2.2 Structure

The basic function of the Arduino programming language is fairly simple and runs in at least two parts. These two required parts, or functions, enclose blocks of statements.
**setup**: A function present in every Arduino sketch. Run once before the loop() function. The setup() function should follow the declaration of any variables at the very beginning of the program. It is the first function to run in the program, is run only once, and is used to set pinMode or initialize serial communication.

**loop**: A function present in every single Arduino sketch. This code happens over and over again—reading inputs, triggering outputs, etc. The loop() is where (almost) everything happens and where the bulk of the work is performed.

### 2.3 Digital I/O Functions

Digital I/O will allow us to read the state of an input pin as well as produce a logical high or low at an output pin. If every potential external connection between a microcontroller and the outside world had a dedicated wire, the pin count for controller packages would be high. The ATmega 328P in the Romeo board has four 8-bit ports plus connections for power, ground and the like, yet it only has 28 physical pins. In general, each bit of a port can be programmed independently; some for input, some for output, or all of them for the same purpose.

1. **pinMode(pin, mode)**

Before we use a port, we need to inform the controller about how it should operate. In the Arduino system, this is usually done via a call to the library function **pinMode**(). Here is a description of the function from online references:
It should be noted that the pin could be a number or variable with a value ranging from 0 to 13 or A0 to A5 (when using the Analog Input pins for digital I/O) corresponding to the pin number printed on the interface board. Furthermore, Digital pins default as input, so you really only need to set them to OUTPUT in pinMode().

2. `digitalWrite(pin, value)`

Once a pin is established as an OUTPUT, it is then possible to turn that pin on or off using the `digitalWrite()` function. Its syntax is as follows:
3. **digitalRead(pin)**

With a digital pin configured as an INPUT, we can read the state of that pin using the `digitalRead()` function. Its syntax is as follows:

```cpp
digitalRead(pin)
Parameters
   pin: the number of the pin you want to read (int)
Returns
   HIGH or LOW
```

The pin can be specified as either a variable or constant (0–13) and the result is either HIGH or LOW.

4. **Example**

The following example reads a pushbutton connected to a digital input and turns on an LED connected to a digital output when the button is pressed. The circuit is shown in Fig. 2.1

![Fig. 2.1 Circuit layout for digital signal read and write](image-url)
2.3 Digital I/O Functions

```
int led = 13; // connect LED to pin 13
int pin = 7;  // connect pushbutton to pin 7
int value = 0; // variable to store the read value

void setup() {
    pinMode(led, OUTPUT);  // set pin 13 as output
    pinMode(pin, INPUT);   // set pin 7 as input
}

void loop() {
    value = digitalRead(pin);      // set value equal to the pin 7 input
    digitalWrite(led, value);      // set LED to the pushbutton value
}
```

2.4 Analog I/O Functions

1. analogReference(type)

The Arduino interface board, however, has a convenient pin called AREF located near digital pin 13 along with a function called analogReference() to provide the Arduino’s ADC a reference voltage other than +5 V. This function will effectively increase the resolution available to analog inputs that operate at some other range of lower voltages below +5 V. The syntax for this function is as follows.

```
analogReference(type)
Parameters
    type: which type of reference to use (DEFAULT, INTERNAL, INTERNAL1V1, INTERNAL2V56, or EXTERNAL)

Returns
    None
```

DEFAULT: the default analog reference of 5 volts (on 5 V Arduino boards) or 3.3 volts (on 3.3 V Arduino boards)
INTERNAL: a built-in reference, equal to 1.1 volts on the ATmega168 or ATmega328 and 2.56 volts on the ATmega8 (not available on the Arduino Mega)
INTERNAL1V1: a built-in 1.1 V reference (Arduino Mega only)
**INTERNAL2V56**: a built-in 2.56 V reference (Arduino Mega only)

**EXTERNAL**: the voltage applied to the AREF pin (0–5 V only) is used as the reference.

The function is only called once in a sketch, but must be declared before analogRead() is used for the first time, making it a suitable candidate for placing in the setup() function. The type specified relates to the kind of reference voltage that we want to use.

2. **analogRead(pin)**

Reads the value from a specified analog pin with a 10-bit resolution. This function works with the above analogy only for pins (0–5). The analogRead() command will return a number including or between 0 and 1023.

```
analogRead(pin)
Parameters
    pin: the number of the analog input pin to read from (0–5)
Returns
    int(0 to 1023)
```

It takes about 100 μs (0.0001 s) to read an analog input, so the maximum reading rate is about 10,000 times a second. Furthermore, analogy pins unlike digital ones, do not need to be first declared as INPUT nor OUTPUT.

3. **analogWrite(pin,value)**

The Arduino also has the capability to output a Digital signal that acts as an Analog signal, this signal is called pulse width modulation (PWM). Digital Pins # 3, # 5, # 6, # 9, # 10, and # 11 have PWM capabilities. To output a PWM signal use the command: analogWrite().
You do not need to call pinMode() to set the pin as an output before calling analogWrite().

4. Example
The following example reads an analog value from an analogy input pin, converts the value by dividing by 4, and outputs a PWM signal on a PWM pin (Fig. 2.2).

Fig. 2.2 Circuit layout for analogy signal read and write
2.5 Advanced I/O Functions

1. `shiftOut(dataPin, clockPin, bitOrder, value)`

Shifts out a byte of data one bit at a time. Starts from either the most (i.e., the leftmost) or least (rightmost) significant bit. Each bit is written in turn to a data pin, after which a clock pin is pulsed (taken high, then low) to indicate that the bit is available. The syntax is as follows.

```cpp
shiftOut(dataPin, clockPin, bitOrder, value)
```

**Parameters**
- `dataPin`: the pin on which to output each bit (`int`)
- `clockPin`: the pin to toggle once the `dataPin` has been set to the correct value (`int`)
- `bitOrder`: which order to shift out the bits; either `MSBFIRST` or `LSBFIRST`. (Most Significant Bit First, or, Least Significant Bit First)
- `value`: the data to shift out (`byte`)

**Returns**
- None
This is known as synchronous serial protocol and is a common way that microcontrollers communicate with sensors, and with other microcontrollers. The two devices always stay synchronized, and communicate at close to maximum speeds, since they both share the same clock line. Often referred to as SPI (synchronous protocol interface) in hardware documentation.

2. **pulseIn(pin,value,timeout)**

Reads a pulse (either HIGH or LOW) on a pin. For example, if the value is HIGH, pulseIn() waits for the pin to go HIGH, starts timing, then waits for the pin to go LOW and stops timing. Returns the length of the pulse in microseconds. Gives up and returns 0 if no pulse starts within a specified time out. The timing of this function has been determined empirically and will probably show errors for longer pulses. Works on pulses from 10 μs to 3 min in length. The syntax is as follows.

```plaintext
pulseIn(pin,value,timeout)

Parameters

- pin: the number of the pin on which you want to read the pulse (int)
- value: type type of pulse to read: either HIGH or LOW (int)
- timeout (optional): the number of microseconds to wait for the pulse to start; default is one second (unsigned long)

Returns

the length of the pulse (in microseconds) or 0 if no pulse started before the timeout
```
Please go to Chap. 4, and refer the example for pulseIn().

3. Example

In this example, we will be using the 74HC595 8-bit shift register, which you can pick up from most places at a very reasonable price. This shift register will provide us with a total of eight extra pins to use. The layout is as follows (Fig. 2.3).

In this example, we increment the currentLED variable and pass it to the bitSet method. The bit is set to the left of the previous one to 1 every time, thereby informing the shift register to activate the output to the left of the previous one. As a result, the LEDs light up one by one.
2.5 Advanced I/O Functions

```c
int latchPin = 12;
int clockPin = 11;
int dataPin = 13;
byte leds = 0;
int currentLED = 0;
void setup() {
    pinMode(latchPin, OUTPUT);
    pinMode(dataPin, OUTPUT);
    pinMode(clockPin, OUTPUT);
    leds = 0;
}
void loop() {
    leds = 0;
    if (currentLED == 7) {
        currentLED = 0;
    } else {
        currentLED++;
    }
    bitSet(leds, currentLED);
    digitalWrite(latchPin, LOW);
    shiftOut(dataPin, clockPin, LSBFIRST, leds);
    digitalWrite(latchPin, HIGH);
    delay(250);
}
```

2.6 Timer Functions

1. `delay(ms)`

Pauses the program for the amount of time (in milliseconds) specified as the parameter. The syntax for the function is as follows.
delay(ms)
Parameters
    ms: the number of milliseconds to pause (unsigned long)
Returns
    None

Time is specified in milliseconds, where a delay of 1000 ms equals 1 s, 2000 ms equals 2 s, and so on. This value can be expressed as a constant or variable in the unsigned long data type.

The use of delay() in a sketch has significant drawbacks. No other reading of sensors, mathematical calculations, or pin manipulations can function during the delay function, so in effect, it brings most other activities to a halt.

2. delayMicroseconds(us)

Rather than a long delay, the delayMicroseconds() function is used to delay for a much shorter time. The syntax is as follows:

delayMicroseconds(us)
Parameters
    us: the number of microseconds to pause (unsigned int)
Returns
    None

Unlike delay(), time here is specified in microseconds, or millionths of a second, where a time period of 1000 µs would equal 1 ms or 0.001 of a second, 10,000 would equal 10 ms or 0.01 of a second, and so on.

3. millis()

Inside the microcontroller on the Arduino board there are three onboard hardware timers that work in the background to handle repetitive tasks like incrementing counters or keeping track of program operations. Each of these timers is already being used in some capacity, usually for handling hardware PWM and system
timing. The millis() function makes use of one of these hardware timers to maintain a running counter of how many milliseconds the microcontroller has been running since the last time it was turned on or reset. Because this function uses a hardware timer, it performs its counting in the background with no impact on the flow or resources of our source code.

```
millis()
Parameters
None
Returns
Number of milliseconds since the program started (unsigned long)
```

By calling the function, it returns a value in milliseconds that can be used like any other variable as part of a conditional test, to perform arithmetic operations, or to be assigned to other variables. Because this function returns a value in an unsigned long data type, it will overflow, or reset to 0, in about 50 days. It can also result in undesired problems if an expression is performed on it using other data types like integers.

4. `micros()`

Where the millis() function returns the current operating time in milliseconds, the micros() function does the same, but in microseconds. This could be used in exactly the same manner as millis(), just on a much smaller scale, effectively returning the value 1000 for every 1 that millis() would return.

```
micros()
Parameters
None
Returns
Number of microseconds since the program started (unsigned long)
```

Unlike millis(), micros() will overflow, or reset back to 0, every 70 min.
2.7 Communication Functions

1. **Serial.begin(speed)**

   Opens the serial port and sets the baud rate for serial data transmission. The typical baud rate for communicating with the computer is 9600, although other speeds are also supported, i.e., 300, 600, 1200, 2400, 4800, 9600, 14,400, 19,200, 28,800, 38,400, 57,600, or 115,200.

   ```
   Serial.begin(speed)
   Parameters
   - speed: set the baud rate
   Returns
   None
   ```

   It should be noted that the digital pins 0 (RX) and 1 (TX) cannot be used at the same time when using serial communication.

2. **Serial.available()**

   Receives the number of bytes (characters) available for reading from the serial port. This is data that has already arrived and been stored in the serial receive buffer.

   ```
   Serial.available()
   Parameters
   - None
   Returns
   the number of bytes available to read
   ```

   Remember, the hardware serial port on the Arduino microcontroller has a buffer that can store up to 128 bytes of information so that it is not lost. If no data is waiting for us, it will return 0. On the other hand, if any data is available, the function will return a value other than 0, which will signify true. We can proceed to read from the buffer.
Serial.available() inherits from the Stream utility class.

3. **Serial.read()**

Reads incoming serial data.

```plaintext
Serial.read()
Parameters
    None
Returns
    the first byte of incoming serial data available (or -1 if no data is available) - int
```

This function simply returns the first byte of information available in the serial buffer. Because of the way our serial communications are structured, each character that we send to the Arduino through the Serial Monitor will be converted to that character’s ASCII character value. For example, if we were to send the Arduino the number 1, instead of receiving the numerical integer 1, the Arduino will actually receive the numerical value 49 corresponding to that character’s ASCII character code.

Serial.read() inherits from the Stream utility class

4. **Serial.print(val)**

Prints data to the serial port as human-readable ASCII text.

```plaintext
Serial.print(val)
Parameters
    val: the value to print - any data type
Returns
    None
```

This command can take many forms. Numbers are printed using an ASCII character for each digit. Floats are similarly printed as ASCII digits, defaulting to two decimal places. Bytes are sent as a single character.
5. **Serial.printIn(val,format)**

Prints data to the serial port as human-readable ASCII text followed by a carriage return character (ASCII 13, or ‘\r’) and a newline character (ASCII 10, or ‘\n’).

```
Serial.printIn(val,format)
```

**Parameters**
- **val**: the value to print — any data type
- **format**: specifies the number base (for integral data types) or number of decimal places (for floating point types)

**Returns**
the number of bytes available to read

The println() function is a little easier to use and helps to clean up the output that we receive from the Serial Monitor. You will often see both the print() and println() functions used in conjunction to format the output, making the text easier to read.

6. **Example**

In this example, two Arduinos are used. The Arduino Uno on the left is our sender and the Arduino Mega on the right is our receiver. We use the Mega to make it easier to display debug information on the computer. The Arduinos are connected together using digitals 0 and 1 (RX and TX) on the Uno and digitals 16 and 17 (RX2 and TX2) on the Mega. The receiver on one needs to be connected to the transmit of the other, and vice versa. The Arduinos also need to have a common reference between the two. This is ensured by running a ground wire (Fig. 2.4).

![Fig. 2.4 The schematic of serial communication](image-url)
The first step is to package the string to be communicated. In general, a packet is comprised of some start byte, a payload (the data you wish to send), and a checksum to validate your data. Here, the packet is: $[0 \times 53] + \text{[counter value]} + \text{[static value]} + \text{[checksum]}$.

**Sender Code**

The simple sender coder below increments our counter and sends our packet.

```cpp
// Sender Information
unsigned char START_BYTE = 0x53; // ASCII "S"

unsigned char counterValue = 0;
unsigned char staticValue = 5;
unsigned char checksum = 0;

void setup() {
    Serial.begin(9600);
}

void loop() {
    // Increment our counter
    counterValue = counterValue + 1;
    // Check for overflow, and loop
    if (counterValue > 250)
        counterValue = 0;
    // Calculate our checksum
    checksum = counterValue + staticValue;
    // Important: Serial.write must be used, not print
    Serial.write(START_BYTE);
    Serial.write(counterValue);
    Serial.write(staticValue);
    Serial.write(checksum);
    // We only need to send a packet every 250ms.
    // If your code starts to get complicated,
    // consider using a timer instead of a delay
    delay(250);
}
```

**Receiver Code**

For the receiver code, we constantly go through the main loop and check whether we have information ready to be read. Once, we receive our first byte we compare it to our expected start byte. If this passes, then we set a flag and wait for the rest of the packet to roll in. Once, we have the expected packet then we read the values in it, calculate our checksum, and then print out the result on our terminal.
// Receiver Information
unsigned char START_BYTE = 0x53; // ASCII "S"
unsigned char counterValue = 0;
unsigned char staticValue = 0;
unsigned char checksum = 0;
boolean syncByteFound = 0; // Sync Byte flag

void setup() {
  Serial.begin(9600);
  Serial2.begin(9600);
}

void loop() {
  unsigned char rxByte = 0;
  unsigned char calculatedChecksum = 0;
  // Check to see if there's something to read
  if (Serial2.available() > 0) {
    // If we're waiting for a new packet, check for the sync byte
    if (syncByteFound == 0) {
      rxByte = Serial2.read();
      if (rxByte == 0x53)
        syncByteFound = 1;
    }
    // If we've found our sync byte, check for expected number of bytes
    if (Serial2.available() > 2) {
      counterValue = Serial2.read();
      staticValue = Serial2.read();
      checksum = Serial2.read();
      calculatedChecksum = counterValue + staticValue;
      // Print out our serial information to debug
      Serial.print("[");
      Serial.print("S");
      Serial.print(")");
      Serial.print(counterValue);
      Serial.print(")");
      Serial.print(staticValue);
      Serial.print(")");
      Serial.print(checksum);
    }
  }
}
2.8 Interrupt Functions

1. attachInterrupt(digitalPinToInterrupt(pin), ISR, mode)

The attachInterrupt() function enables hardware interrupts and links a hardware pin to an ISR to be called when the interrupt is triggered. This function also specifies the type of state change that will trigger the interrupt. Its syntax is as follows:

```
attachInterrupt(digitalPinToInterrupt(pin), ISR, mode)
```

**Parameters**

- interrupt: the number of the interrupt (int)
- pin: the pin number
- ISR: the interrupt service routine (ISR) to call when the interrupt occurs; this function must take no parameters and return nothing. This function is sometimes referred to as an interrupt service routine.

**mode:** defines when the interrupt should be triggered. Four constants are predefined as valid values:

- LOW to trigger the interrupt whenever the pin is low,
- CHANGE to trigger the interrupt whenever the pin changes value
- RISING to trigger when the pin goes from low to high,
- FALLING for when the pin goes from high to low.

**Returns**

None
Normally, you should use digitalPinToInterrupt(pin), rather than place an interrupt number directly into your sketch. The specific pins with interrupts, and their mapping to interrupt numbers vary for each type of board. On the DFrobot Romeo board, there are two possible hardware interrupts, 0 (for digital pin 2) and 1 (for digital pin 3).

Four possible modes are shown in Fig. 2.3, which include LOW, CHANGE, RISING, and FALLING (Fig. 2.5).

2. detachInterrupt(interrupt)

In some cases, we might need to change the mode of an enabled interrupt. For example, we may change the mode from RISING to FALLING. For this, we need to first stop the interrupt by using the detachInterrupt() function. Its syntax is as follows:

```cpp
detachInterrupt(interrupt)
```

Parameters

- `interrupt`: the number of the interrupt to disable

Returns

- None
With only one parameter to determine which interrupt we are disabling, this parameter is specified as either 0 or 1. Once the interrupt has been disabled, we can then reconfigure it using a different mode in the attachInterrupt() function.

3. `interrupts()`

All interrupts in Arduino can be enabled by the function `interrupts()`. The syntax is as follows:

```cpp
Interrupts()
Parameters
   None
Returns
   None
```

Interrupts allow certain important tasks to run in the background and are enabled by default. Some functions will not work while interrupts are disabled, and incoming communication may be ignored. Interrupts can slightly disrupt the timing of a code, however, and may be disabled for particularly critical sections of code.

4. `noInterrupts()`

To deactivate all interrupts, we can use the function `noInterrupts()`. The syntax is as follows:

```cpp
noInterrupts()
Parameters
   None
Returns
   None
```

5. **Example**

In this example, we blink the built-in LED every 500 ms, during which time both interrupt pins are monitored. When the button on the interrupt 0 is pressed, the value for micros() is displayed on the Serial Monitor, and when the button on the interrupt 1 is pressed, the value for millis() is displayed (Fig. 2.6).
```cpp
#define LED 13
void setup() {
    Serial.begin(9600);
    pinMode(LED, OUTPUT);
    attachInterrupt(0, displayMicros, RISING);
    attachInterrupt(1, displayMillis, RISING);
}
void loop() {
    digitalWrite(LED, HIGH);
    delay(500);
    digitalWrite(LED, LOW);
    delay(500);
}
void displayMicros() {
    Serial.write("micros()=");
    Serial.println(micros());
}
void displayMillis() {
    Serial.write("millis()=");
    Serial.println(millis());
}
```

Fig. 2.6 The circuit for interrupts and time functions
2.9 Math Functions

The Arduino language supports many math functions which make it possible to perform sophisticated data processing in a data logger sketch that would otherwise have to be performed offline in some other software application.

1. **min(x,y)**

   Calculates the minimum of two numbers

   ```
   min(x,y)
   Parameters
   x: the first number, any data type
   y: the second number, any data type
   Returns
   The smaller of the two numbers
   ```

2. **max(x,y)**

   Calculates the maximum of two numbers.

   ```
   max(x,y)
   Parameters
   x: the first number, any data type
   y: the second number, any data type
   Returns
   The larger of the two numbers
   ```
3. **abs(x)**

Computes the absolute value of a number

```
abs(x)
Parameters
  x: the number
Returns
  x: if x is greater than or equal to 0.
  -x: if x is less than 0.
```

Because of the way the abs() function is implemented, avoid using other functions inside the brackets, it may lead to incorrect results.

4. **Trigonometric functions**

The trigonometric functions include sin(rad), cos(rad), and tan(rad). All trigonometric functions accept as input and return as output angles in radians, not degrees: radians = degrees × π/180 and vice versa to convert radians back to degrees.

5. **pow(base,exponent)**

Calculates the value of a number raised to a power. pow() can be used to raise a number to a fractional power. This is useful for generating exponential mapping of values or curves.

```
pow(base,exponent)
Parameters
  base: the number (float)
  exponent: the power to which the base is raised (float)
Returns
  The result of the exponentiation (double)
```
6. \texttt{sqrt}(x)
Calculates the square root of a number.

\begin{verbatim}
\texttt{sqrt}(x)
Parameters
  x: the number, any data type
Returns
  double, the number's square root
\end{verbatim}

7. \texttt{constrain}(x,a,b)
Constrains a number to be within a range.

\begin{verbatim}
\texttt{constrain}(x,a,b)
Parameters
  x: the number to constrain, all data types
  a: the lower end of the range, all data types
  b: the upper end of the range, all data types
Returns
  x: if x is between a and b
  a: if x is less than a
  b: if x is greater than b
\end{verbatim}
8. \texttt{map(value,fromLow,fromHigh,toLow,toHigh)}

Remaps a number from one range to another. That is, a value of \texttt{fromLow} would be mapped to \texttt{toLow}, a value of \texttt{fromHigh} to \texttt{toHigh}, values in-between to values in-between, etc.

\begin{verbatim}
map(value,fromLow,fromHigh,toLow,toHigh)
Parameters
  value: the number to map
  fromLow: the lower bound of the value's current range
  fromHigh: the upper bound of the value's current range
  toLow: the lower bound of the value's target range
  toHigh: the upper bound of the value's target range
Returns
  The mapped value
\end{verbatim}

9. \texttt{random(min,max)}

The \texttt{random()} function returns a semi-random number up to the parameters specified. If no parameters are specified, it will return a value in the signed long data type, with a range of \(-2,147,483,648–2,147,483,647\). Its syntax is as follows:

\begin{verbatim}
random(min,max)
Parameters
  min: lower bound of the random value, inclusive (optional)
  max: upper bound of the random value, exclusive
Returns
  a random number between min and max
\end{verbatim}

The \texttt{random()} function will assume a value of 0 as its minimum value.
10. **Example**

In this example, we create a sine wave and configure the brightness of the LED to follow the path of the wave. This is what makes the light pulsate in the form of a sine wave instead of just illuminating up to full brightness and back down again (Fig. 2.7).

The codes are as follows (Fig. 2.7)

```cpp
int ledPin = 11;
float sinVal;
int ledVal;
void setup() {
  pinMode(ledPin, OUTPUT);
}
void loop() {
  for (int x = 0; x < 180; x++) {
    // convert degrees to radians
    // then obtain sin value
    sinVal = sin(x * (3.1412 / 180));
    ledVal = int(sinVal * 255);
    analogWrite(ledPin, ledVal);
    delay(25);
  }
}
```

<tr>
<td>int</td>
<td>Integer values, such as 123</td>
</tr>
<tr>
<td>float</td>
<td>Decimal values, such as 1.15</td>
</tr>
<tr>
<td>char[]</td>
<td>String values, such as “Arduino”</td>
</tr>
<tr>
<td>HIGH</td>
<td>Digital pin with current</td>
</tr>
<tr>
<td>LOW</td>
<td>Digital pin with no current</td>
</tr>
<tr>
<td>INPUT</td>
<td>Pin can only be read</td>
</tr>
<tr>
<td>OUTPUT</td>
<td>Pin can only be set</td>
</tr>
<tr>
<td>A0–A7</td>
<td>Constants for analog pins; varies by board</td>
</tr>
<tr>
<td>0–13</td>
<td>Value for digital pins; varies by board</td>
</tr>
<tr>
<td>analogRead()</td>
<td>Returns analog pin value (0–1023)</td>
</tr>
<tr>
<td>analogWrite()</td>
<td>Sets analog pin value</td>
</tr>
<tr>
<td>digitalRead()</td>
<td>Returns digital pin value (HIGH or LOW)</td>
</tr>
<tr>
<td>digitalWrite()</td>
<td>Sets digital pin value (HIGH or LOW)</td>
</tr>
<tr>
<td>Serial.begin()</td>
<td>Initializes serial monitor</td>
</tr>
<tr>
<td>Serial.print()</td>
<td>Logs message on serial monitor</td>
</tr>
<tr>
<td>Serial.println()</td>
<td>Logs message on serial monitor with new line</td>
</tr>
<tr>
<td>delay(ms)</td>
<td>Adds a wait in processing</td>
</tr>
<tr>
<td>setup()</td>
<td>Standard Arduino function called once</td>
</tr>
<tr>
<td>loop()</td>
<td>Standard Arduino function called repeatedly</td>
</tr>
<tr>
<td>if</td>
<td>Checks for a true/false condition</td>
</tr>
<tr>
<td>if … else</td>
<td>Checks for a true/false condition; if false goes to else</td>
</tr>
<tr>
<td>//</td>
<td>Single-line comment</td>
</tr>
<tr>
<td>/* */</td>
<td>Multiline comment</td>
</tr>
<tr>
<td>#define</td>
<td>Defines a constant</td>
</tr>
<tr>
<td>#include</td>
<td>Includes an external library</td>
</tr>
